The situation is otherwise for whole-time medical officers and research workers. In the past they have been less favoured and in their case rewards for special merit may be more fairly assessed and more reasonably granted.

I do not believe that "the considerable sum of money allocated for these awards" (Dr. H. E. A. Boldero, September 10, p. 594) will blind part-time consultants to their many objectionable features.—I am, etc.,

Chelmsford. H. BATHURST NORMAN.

Surfeit of Diplomas

SIR,—Now that thoughts are directed at last towards planning a satisfactory medical education to form a sound basis for the complicated structure of medical practice in this country, it is meet that all of us who feel strongly on the matter should contribute. My contribution here is on the problem of multiple academic degrees. Generally speaking, all concerned are agreed that a change must come about; indeed, it has been forced on us by events. However, in putting it into effect there are two opposing camps: (1) The conservatives, who believe in keeping multiple degrees and would merely improve things as they are; (2) the radicals, who advocate the abolition of multiple degrees and the adoption of the American and Continental systems. Recognition of the specialist and teacher would be by work done and published, and by common agreement among colleagues and patients.

It seems to me, as a specialist struggling with the odd and wasteful process supported by this first group and reluctant to approve changes supported by the second group, that the near-ideal compromise has not been stressed sufficiently. British medicine has a long and glorious tradition, and has maintained its high standard throughout the world for many years. Therefore, to imitate others seems like a retrograde step. At the same time all criticism recently levelled at the multiple degrees, particularly the M.R.C.P., with which I am most acquainted, is sound and demands urgent attention. A compromise might perhaps be reached on the following scheme.

(1) The standard of the qualifying degree throughout the British Isles should be unified, and perhaps modelled on the M.B.(London). The degree might be taken anywhere in the universities, but the examination and its administration should be centralized. This would abolish immediately the necessity of having such examinations as the M.R.C.P. and F.R.C.S. as they now stand, the only use of which is to make sure that the prospective consultant is a sound doctor. Incidentally, by such a measure the level of medical education and training for general practitioners will be raised, and it would be unnecessary for the better ones to prove that they are better by taking a Membership or a Fellowship—or, worse, some extra specialist degree bearing no relation whatever to their interest and practice.

(2) Those intending to practise in some specialist branch of surgery or medicine would then proceed on a postgraduate course of training for a sufficiently long period—at least two and a half years—culminating in some such specialist degree as the D.P.M., D.C.H., or M.R.C.O.G. These degrees also should be uniform and centralized to prevent present anomalies. This would ensure that a man practising as a specialist received adequate training in his chosen specialty. Progress from this stage (Registrar Class I) onwards would be entirely on personal merits, clinical and scientific published work, and the acknowledgments both of colleagues and patients. No further time should be wasted in the acquisition of degrees.

(3) Those intending to specialize in major surgery or medicine would proceed on a similar course, perhaps of longer duration—say, five years—and culminating in an examination for Membership or a Fellowship. Here again further progress should be on the principles mentioned above.

(4) Those intending to become teachers or research workers, or those who wished to improve whatever status and knowledge they had, should have an opportunity to take an M.D. or an M.S., or the equivalent, by thesis and examination on their thesis only.

Thus, a pathologist would have an M.B. and an M.D. in pathology; a psychiatrist an M.B. and a D.P.M.; a physician an M.B. and M.R.C.P.; a teacher in paediatrics an M.B., D.C.H., and M.D.(Paediatrics); and a teacher of medicine an M.R.C.P., M.D., and eventually a Fellowship. There should be no hindrance to the election to an Honorary Fellowship to all those who, in the opinion of the College, deserve such a distinction. I would suggest that some such scheme would do away with most of the evils of multiple degrees and yet preserve the essentials in the traditional system of British medicine; it would satisfy all but the most sanguine.—I am, etc.,

D. CAPPON,

London, S.E.27. L.M.S.S.A., L.R.C.P., M.R.C.S.(England), M.B., B.S.(London), M.R.C.P.(Edinburgh), D.P.M.(England).

SIR,—I read your erudite article on the above-mentioned theme (September 3, p. 520) with considerable interest. I feel that never was there a time when various public bodies were so degree- and diploma-conscious as they are to-day, and seek to equate an impressive string of appendages to one's name with clinical prowess which may by no means be the case.

In this connexion is there not perhaps a surfeit of final qualifications? In a typical London medical school students are preparing for at least five different qualifying "finals"—those of the older universities, London University, the Royal Colleges, and the Society of Apothecaries. Matters are complicated by the fact that they are all held at different times of the academic year. I hinted in a letter published in 1947 that it might be worth having one qualifying examination, as is the rule on the Continent, and that it be held not more than twice a year so as to disturb as little as possible didactic continuity.

All clinical students work under the same chiefs, attend the same lectures and out-patient classes, and frequent the same ward rounds and operating lists, and yet are working for different examinations. I do feel that standardization of the finals is a very urgent academic reform which would be appreciated by clinical teachers throughout the country. When all is said and done, the actual standards of the various finals do not vary an enormous amount, as candidates take the same subjects in all cases. Perhaps the M.R.C.S. is a trifle stiffer than the B.S., and the obstetric examination of the Society of Apothecaries is probably the stiffest obstetric final of any qualifying body, owing to its process of elimination after the paper and *viva voce* parts of the examination.

All these finals make for bad feeling between students, the older universities tending to frown on London University and the university candidate feeling superior to those taking the various qualifying diplomas of greater historic origin.

I feel overseas visitors to Britain must be well-nigh bewildered by the long list of British medical degrees and diplomas offered by numerous academic bodies. Academic medicine could well be simplified.—I am, etc.,

J. B. GURNEY SMITH.

Epsom.

Tuberculosis: Certain Unexplained Mortality Figures

SIR,—Mr. Walter Elliot has drawn attention (August 6, p. 297) to the rise in the death rates for pulmonary tuberculosis in Scotland since 1939, and has invited suggestions for solving the problem.

Of the three possible types of causes for an increase in the death rate due to tuberculosis Mr. Elliot has mentioned environmental and bacteriological causes. A third group of causes for the increase in the death rate comprises those of a statistical nature. Apart from the effect of a rise in the age-specific death rate (civilians) for the age groups 15–34, due to recruitment of the healthier individuals, there is another type of statistical cause which may account for a good deal of the rise in death rates.

Not only can the depletion in the number of persons at risk in certain age groups and the resulting increase in the age-specific death rate push up the crude death rate, but an increase in the population at risk in the critical age groups, without a change in the age-specific death rates, can have the same effect on the crude death rate; and it is the crude death rates only with which Mr. Elliot's analysis is concerned.

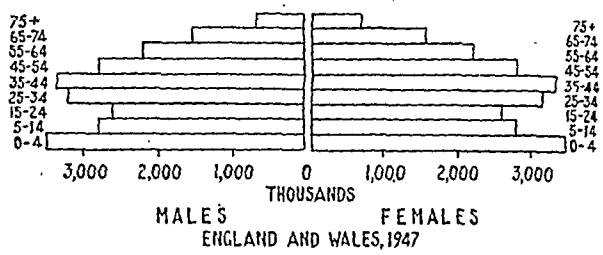
That something of this type of cause is responsible for the increase in the death rate in question becomes apparent if we examine (1) the change of death rates due to tuberculosis with age, and (2) the change of the age structure of the population in Scotland within the relevant period.

(1) The highest death rates due to tuberculosis of the respiratory system for Scotland in 1945 are for males in the ages from 15–45, and for females from 15–34. We can get an idea of the age distribution of deaths due to tuberculosis by calculating the median age of death together with the interquartile range, giving the ages around the median age within which 50% of deaths due to tuberculosis occurred. For Scotland in 1945 we then find for males a median age of 38.3 with an interquartile range from 25.4–52.8, and for females a median age of 26.8 with an interquartile range of 19.5–33.0 years.

(2) The change of the age structure of the population of Scotland, on the other hand, can be epitomized by saying that Scotland has an ageing population. That is to say that the older age groups are becoming increasingly important. By "older" is here not meant only the age groups of the very old, say from 65 upwards; the ageing of a population is characterized by a relative increase of all age groups except those of infancy and childhood.

This can be visually demonstrated by using the concept of the so-called population pyramid (Crew, *Measurements of the Public Health*, p. 32). Looking now at the population pyramid for Scotland, we find an excess of persons in what has been shown above to be the most critical periods of death from pulmonary tuberculosis—i.e., from 15–55, males and females together. This must have the effect, by itself and even without an increase in the age-specific death rate due to tuberculosis, of pushing up the crude death rate due to tuberculosis, because the age groups for which the risk was greatest have now greater weight than in former times.

An explanation of this kind does not, of course, exclude a simultaneous rise in the age-specific death rates. It would, however, strengthen the argument put forward here if it could be shown that the change in the age-specific death rates during these years was less pronounced than that in the crude death rate. The Table gives the civilian death rate per 100,000 of the population at the critical ages from 1939–46.



Age Groups		1939	1940	1941	1942	1943	1944	1945	1946
15–24	M	64	95	89	102	89	100	102	84
	F	102	111	134	142	143	143	124	137
25–34	M	82	114	129	114	136	132	142	94
	F	33	97	96	99	97	103	120	128
35–44	M	97	113	107	95	113	106	108	102
	F	48	52	53	51	51	53	42	53
45–54	M	106	125	115	112	110	102	101	119
	F	36	34	36	32	25	21	27	29

The features of this Table which would seem to confirm the explanation given above are, briefly:

(1) The age-specific death rates for the age groups 15–34 years, whose increase up to 1945 must no doubt be partly put down to the recruitment of healthy individuals from 1939 onwards, show for males in 1946 a surprisingly deep drop. Since this drop is not reflected in the overall death rate for 1946 it would seem to support the statistical explanation given here. Female death rates, however, in these age groups show no such drop, and we must assume some physical cause to be operative here.

(2) There is no consistent rise in the death rates for the age groups 35–54.

The question now arises why such an effect of an ageing population upon the death rate due to tuberculosis should be less pronounced for England and Wales, which, as is well known, have also an ageing population. The population pyramid for England and Wales for 1947 seems to provide the answer. The pyramid is based upon

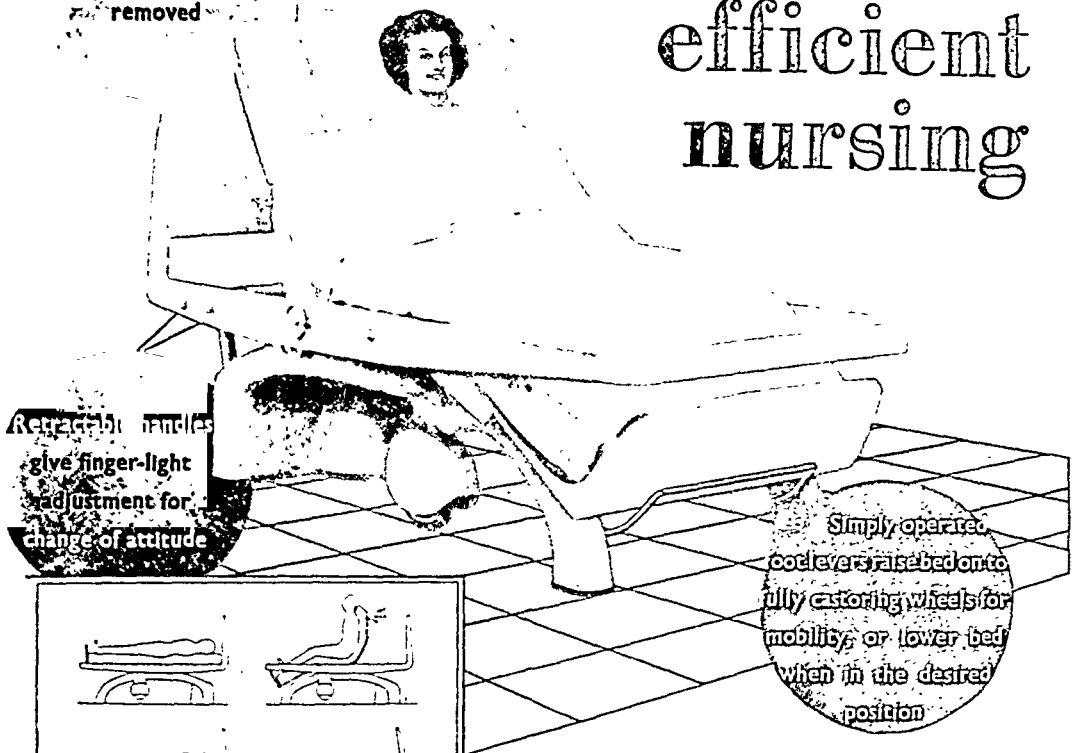
ENGLAND AND WALES, 1947

the civilian population estimated for the middle of 1947 by the Registrar-General, males and females together, and is made symmetrical because I have not before me reliable figures for males and females separately.

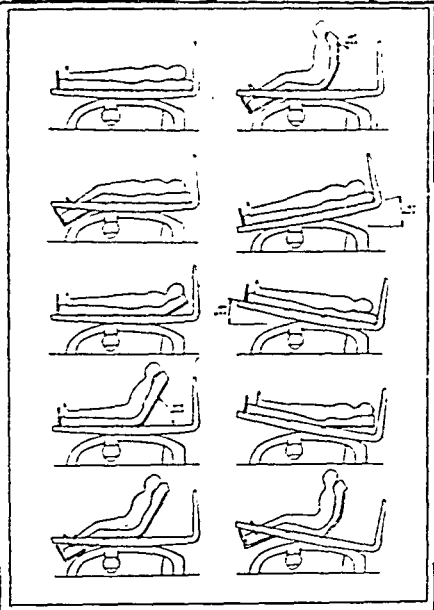
The critical age groups, 15–35 years, present a very different picture in the two pyramids for England and Scotland. Whereas they are bulging out in the pyramid for Scotland, indicating greater weight in these age groups, they are receding in the pyramid for England and Wales. This means that the purely statistical cause for the increase in the death rate due to tuberculosis—viz., the greater weights of the critical age groups—would not operate in England.—I am, etc.,

Bristol, 8. G. HERDAN.

Myxoedematous Madness



SIR,—Though some may find the title of "Myxoedematous Madness" (September 10, p. 555) euphonious or striking, it has in my mind the serious defect that it strongly suggests that a specific kind of psychosis due only to myxoedema exists. This possibility seems to be scouted in your annotation (p. 587), where you appear to support the suggestion that myxoedema only serves to precipitate latent psychotic illness. On the other hand, Dr. R. Asher, despite the wide range of psychotic symptoms which he ascribes to myxoedema, considers the myxoedema to be the basic cause of psychosis in his 14 patients, and infers that the pattern of psychotic disorder can also be ascribed to myxoedema. Further than this, and apparently on account of his observation of these 14 cases, he suggests that all the common psychoses have a similar underlying cause in that they are determined by organic disease.



Let us all thank Dr. Asher for telling us that a frank psychosis may occur in association with myxoedema, and for describing so lucidly his findings in 14 cases. I shall now hope to earn the gratitude of the profession by pointing out that the average doctor must also be on his guard against the occurrence of psychosis in association with any physical disease: I shall further try to gain thanks by showing that this association does not necessarily imply that one disease is the cause of the other.

In a city of about 150,000 female inhabitants, all but a negligible number of psychotics were admitted to one hospital. In three years five cases of myxoedema with psychosis were seen: the incidence in that period is thus about 1.1 per 100,000 per year of the total female population in that city. Of these cases one could best be described in Zondek's words, "mixed thyroidism," as she showed clinical signs of Graves's disease, myxoedema, and melancholia; two were cases which developed after partial thyroidectomy; the other two cases were straightforwardly myxoedematous. All the patients suffered from melancholia, none was cured by thyroid alone over a prolonged period—although this proves nothing—and all required electroplexy. Two patients in particular showed projected delusionary formations and other paranoid trends, but a study of the psychopathology showed clearly that these means of discharging tension were secondary products of a melancholic state.

I do not know the incidence of myxoedema among the general population, but I would suggest that psychosis with myxoedema in women is not more common than one would

Designed for efficient nursing

★ Development of the "Magbed" has been guided by the authorities of Charing Cross Hospital, and the functions of the bed fully meet the requirements of nursing and medical staff.

★ All nursing effort, whether in dealing with bed or patient, is reduced to a minimum by simplicity of controls which give speedy yet gentle operation from either side of the bed.

★ Little effort is needed to move the "Magbed," as it is only half the weight of the existing semi-mobile bed, and movement of bed and patient is achieved quickly and silently by one unassisted nurse.

★ Completely enclosed mechanical parts, and the absence of dust-traps in the smooth design, provide for easy cleaning and maintenance of hygiene.

The versatile "MAGBED"

Designed and manufactured by ESSEX AERO Limited,
The Airport, Gravesend, Kent

THE INTRAVAGINAL TAMPON IN MENSTRUAL HYGIENE

An important clinical study

Significant facts obtained by the close observation of 25 parous and nonparous women

In view of the increasing use of the intravaginal tampon for the absorption of the menstrual flow, the following important study was undertaken to determine whether or not this method of sanitary control is safe and not prejudicial to health.

Twenty-five women—parous and nonparous—were selected and were under daily institutional observation during two successive catamenial periods. Ranging in age from twenty-one to forty-five, some had previously used tampons, others had not.

The following summary indicates clearly the findings of the study.

1. In not a single instance was there any evidence of local irritation brought about by the use of the tampons.

Reprinted from the Medical Record, U.S.A. for May, 1942

2. No uterine cramps, suggestive of block of the uterine flow or damming back into the tubes were reported in any case of this series.

3. No bladder irritation was reported.

4. The average number of tampons used in a period was ten.

5. In cases in which a cervical erosion was present, neither the amount of bleeding nor the character of the erosion was altered by the use of the tampons.

6. There was no appreciable difference in the bacterial flora of the vagina and cervix, as determined by smear and culture, before menstruation and after the use of the tampons during the menstrual period.

7. There was no appreciable difference in the pH of the vaginal or cervical secretions before menstruation and after the use of the tampons during the period.

8. Absolute comfort and complete absorption of the flow was obtained by the proper correlation of the size of the tampon with the length and calibre of the vagina.

9. *The evidence is conclusive that the tampon method of menstrual hygiene is safe, comfortable and not prejudicial to health.*

TAMPAX

If you are not acquainted with Tampax, descriptive literature and samples of both absorbency sizes will gladly be sent on request.

MEDICAL INQUIRIES: TAMPAX LTD., 110 JERMYN ST., S.W.1

POLYCREST

ANTIPRURITIC CREAM

THE "VICIOUS CIRCLE" OF PRURITUS

In the past in the treatment of pruritic conditions counter-irritants were employed, which merely superimposed pain on itching. To-day it is realized that antipruritic therapy can only be effective if it is not only curative but also breaks the 'vicious circle' of itching—scratching—infection—more itching—and so on.

A CAUSAL AND SYMPTOMATIC THERAPY

This modern approach to the problem is embodied in Polycrest Antipruritic Cream, which combines the high bactericidal and fungicidal properties of Phenylmercuric Nitrate with the prompt and prolonged surface anaesthetic action of Amethocaine and Benzocaine, thereby affording simultaneous causal and symptomatic therapy.

INDICATIONS

Pruritus Ani, Haemorrhoids, Anal Eczema, Diabetic Pruritus and other pruritic conditions of diverse origins, including Tinea Infections.

FORMULA:

Phenylmercuric Nitrate	..	*0.25%*
Amethocaine	.. ..	*0.50%*
Benzocaine	.. ..	*5.00%*
Cream Base	.. ..	q.s.

Professional samples and literature are gladly sent on request

CLINICAL PRODUCTS LTD
RICHMOND, SURREY, ENGLAND

expect it to be, with the knowledge in mind that: (1) myxoedema occurs most often (78% of all adult cases) in women between 30 and 50; (2) most cases of female melancholia occur between these ages, with the peak at 45; (3) myxoedema is a "trigger" *par excellence* in causing stress. It has objectionable effects in itself, and it often causes the members of the sufferer's family to lose patience with her and bully her.

With this experience in my mind, I find Dr. Asher's opening sentence to be much exaggerated in two particulars—namely, "Myxoedema is one of the most important . . . and one of the most frequently missed causes of organic psychoses." I cannot think it anything but misleading, in the present state of our knowledge, to call it an organic psychosis. That psychosis with myxoedema is little known and that little is written about it I would ascribe primarily to its relative infrequency, and secondarily to the general ignorance of certain physicians of psychiatric states. Lack of knowledge is daily demonstrated of, for example, mental change associated with hyperthyroidism, rheumatism, alimentary disease, epilepsy, cardiac disease, and other pathological states too numerous to mention. For this I do not blame them but the medical schools and their psychiatric colleagues: though to be sure a physician would not be ill advised first to consult colleagues before he rediscovered something forgotten in the field of psychiatry.

It is undeniable that Dr. Asher has rendered a valuable service in reminding us of the occurrence of psychosis with myxoedema, and in giving us such interesting and illuminating descriptions and photographs. I sincerely hope, with everyone else, that those of us who are undoubtedly missing cases of myxoedema, with or without psychosis, will successfully bear these thoughts in mind. At the same time I believe he has done much to spoil his good work by coming to certain conclusions, which he has stated, without adequate evidence to support them. In fact I consider these conclusions to be retrograde and founded upon a prejudice—that same prejudice which has sent thousands of workers in a fruitless, endless search, like the search for the philosopher's stone, for the physical causes of schizophrenia, paranoia, and the affective psychoses, while they ignored the gold of psychopathology which was theirs for the trouble of a few questions.

In conclusion, Sir, may I remark, apropos your annotation, that the mental symptoms of myxoedema are not of the same nature as those of senile deterioration?—I am, etc.,

Sutton, Surrey. E. B. DAVIES.

Myxoedema and Basal Metabolism

SIR,—Errors in estimating the basal metabolism can probably account for the statement made by Dr. R. Asher (September 10, p. 555): "I have seen many cases of myxoedema with normal or raised B.M.R."

Observations and determinations on many cases of frank and of so-called masked myxoedema, using the surface area measurements and Aub-DuBois standards, amply confirm the views of such an authority as Dr. J. H. Means[1]: "The failure to find a metabolic level as low as minus 35 when the clear-cut picture of myxoedema is present is very unusual." When the myxoedema is not clear-cut clinically I have found the specific action of thyroid on the basal metabolism of value.[2]

Many errors of a technical nature can arise in estimating a basal metabolism, and it is unfortunate that the final result of plus or minus a certain figure should only be looked at and accepted as being necessarily accurate.

In the same way a case of diabetic coma with a reported blood sugar of 90 mg.% in the first instance should not be recorded as an unusual case of diabetes, nor should blood sugars be considered of no value in diagnosing this condition. It seems more reasonable to suspect an error in the blood sugar determination.—I am, etc.,

Sensitivity to Streptomycin

SIR,—The following brief particulars about two nurses who are sensitive to streptomycin may be of interest and help to others in hospitals where similar difficulties are being encountered.

A male nurse frequently got puffiness round the eyes and a vesicular dermatitis, especially on the arms, when working on a tuberculosis ward where streptomycin is used in moderate quantities, and his allergic manifestation occurred even when the nurse did not himself administer streptomycin. At first some doubt was entertained whether it really was streptomycin that was responsible. A patch test with 1:1,000 streptomycin produced no conclusive evidence and no local erythema developed at the site of the test, but when an intradermal test was used by means of 25 mg. streptomycin in 0.1 ml. of sterile water the allergic reaction was immediate and alarming. This was a general reaction, with no local erythema at the site of the injection: there was widespread vesicular dermatitis, subcutaneous oedema, and puffiness of the eyes.

The other nurse was sensitive to a much milder degree. Her patch test also gave no local reaction, but following 25 mg. of intradermal streptomycin a similar allergic reaction of much milder nature followed several hours afterwards.

The points that have emerged from this experience are that a nurse may exhibit sensitivity to streptomycin even though care has been taken to avoid handling the drug; that intradermal sensitivity tests to streptomycin may result in an alarming allergic reaction; and that the local reaction may be negative even though the general one is obvious. This disadvantage of streptomycin may be rare, but when it occurs is hard to mitigate or prevent. This note is written in the hope that by reporting experiences some way of protecting persons sensitive to streptomycin may be found. I am indebted to Dr. P. S. Feeny and Dr. A. D. Porter, visiting dermatologists, for advice.—I am, etc.,

Braintree, Essex. M. C. WILKINSON.

Pavlov and Conditioned Reflexes

SIR,—From my school days upwards I have been familiar with the maxim *De mortuis nil nisi bonum*. Yet Professor E. D. Adrian's article and your leader (September 10, pp. 553, 584) fail, in my opinion, to draw adequate attention to the immense amount of harm and confusion of thought which have resulted from Pavlov's doctrine of conditional reflexes.

Pavlov introduced the term "conditional reflex" in a paper entitled "Experimental Psychology and Psychopathology in Animals" read before the International Congress of Medicine in Madrid in April, 1903. The term "conditional," though adhered to in French and German translations, was altered in English and American translations to "conditioned," and the curse thereof remains with us even unto this day. True, Pavlov did excellent work on the physiology of the digestive system, for which he was awarded a Nobel prize, but he was no psychologist. His co-worker, Professor Y. P. Frolov, records that Pavlov fined any laboratory attendant who dared to suggest that the subjective or mental state of a dog might influence its reactions to the food it was offered. To Pavlov everything (love, hate, jealousy, and fear) was explicable in terms of reflex. He even wrote about a "reflex of freedom," and so on and so forth. Yet later he was forced to admit that animals proved susceptible to suggestion. His experimental dogs were kept in unnatural seclusion more rigid than any solitary confinement in prison, and psycho-analysts have never so isolated their patients during treatment as did Pavlov his dogs.

Were it not that the mistakes men make—even great men—often live after them one might henceforth for ever hold one's peace; but lesser lights have so used and abused Pavlov's work as to confuse issues and offer foolish explanations of phenomena that I feel constrained to utter protest. For instance, in my specialty I have come across the so-called conditioned reflex treatment of alcoholists. The punitive and disgust factors in this treatment are all too obvious, and if drastic punishment were able to cure the offender here, surely, should be an example of it. Yet unless the underlying motivations of this or any other line of misconduct be got under control no permanent readjustment can be effected. This is slowly becoming apparent even to those who engage in the treatment just mentioned.

to mobilize the quiescent stores of fat in the body and the tissue fluids. Restriction of liquids is especially important to secure dehydration. The effect can be observed when a dry diet is prescribed. The "eat as much as you like" does not apply to the liquids.

An advantage of this sort of diet is that the circulation is stimulated as a result of increased tissue metabolism. The system is obliged to make up the lack of the substances missing by its own stores, mobilizing alternately fat, carbohydrates, or proteins. Providing and preparing the necessary dishes is simple and control is easier. This is important, because hearty eaters are as prone to cheat as drug addicts. It is a well-known fact that patients on controlled diet in hospitals or nursing-homes lose much more weight than those who try to keep on a diet at home. It is not necessary to measure calories, but it should be kept in mind that reducing diets below 1,000 calories are only possible if the patient is kept in bed, and at around 1,500 calories it is absolutely necessary to avoid depletion of vitamins by supplying the daily amount in the form of suitable preparations.

If a weekly loss of about four pounds is achieved for a few weeks the "zigzag" diet may be stopped and replaced by the one recommended by Marriott.—I am, etc.,

Budapest. EMERIC DOMANY.

Weight Changes in Pregnancy

SIR,—Under "Notes and Comments" (August 6, p. 346) reference was made by Dr. F. R. Kinkead Allen to an article written by Dame Louise McIlroy and myself (*J. Obstet. Gynaec. Brit. Emp.*, 1937, **44**, 221). This reference was that in 1,000 cases the average total gain in weight among primiparae was 11 lb. 3 oz. (5 kg.) and for multiparae it was 11 lb. 7 oz. (5.2 kg.). It was not stated over what period of pregnancy the observations for these weight gains were made. Reference was also made to Chesley's article on weight changes (*Amer. J. Obstet. Gynec.*, 1944, **48**, 565), but the period of pregnancy during which these observations were made was also omitted.

Your readers might be interested to know that our records were made during the last 16 weeks of pregnancy, while Chesley's covered the last six months. In our series of 1,000 cases the average weight gain was 11 lb. 4½ oz. (5.1 kg.); in Chesley's series the figure was 23.5 lb. (10.6 kg.).

The results of another investigation carried out by one of us during the war on weight changes in pregnancy and infant birth weight are shown in tabular form below.

Average Weight Gains in Pregnancy and Birth Weights of Infants

	Average Total Gain in Weight in Pregnancy				
	For 704 Primiparae		For 296 Multiparae		For 1,000 Cases
Pre-war period: From 24th week of pregnancy*	11 lb. 2 oz. (5·05 kg.)		11 lb. 7 oz. (5·19 kg.)		11 lb. 4½ oz. (5·12 kg.)
	For 547 Primiparae		For 312 Multiparae		For 859 Cases
War period: From 20th week of pregnancy†	14 lb. 6 oz. (6·525 kg.)		12 lb. 15 oz. (5·868 kg.)		13 lb. 14 oz. (6·294 kg.)
	Average Weight of Babies in the Above Cases				All Infants
	Female	Male	Female	Male	
Pre-war period	6 lb. 15 oz. (3·144 kg.)	7 lb. 4 oz. (3·29 kg.)	7 lb. 5 oz. (3·318 kg.)	7 lb. 6 oz. (3·346 kg.)	7 lb. 5 oz. (3·318 kg.)
War period	7 lb. 4½ oz. (3·304 kg.)	7 lb. 6 oz. (3·346 kg.)	7 lb. 8 oz. (3·402 kg.)	7 lb. 11½ oz. (3·5 kg.)	7 lb. 7½ oz. (3·388 kg.)

* These analyses were made from the case notes of patients attending the antenatal clinics of the Royal Free Hospital, London, and Thorpe Coombe Maternity Hospital, Walthamstow, London.
† Thorpe Coombe cases only.

London, E.17. HELEN E. RODWAY.

Manipulation for Rheumatism

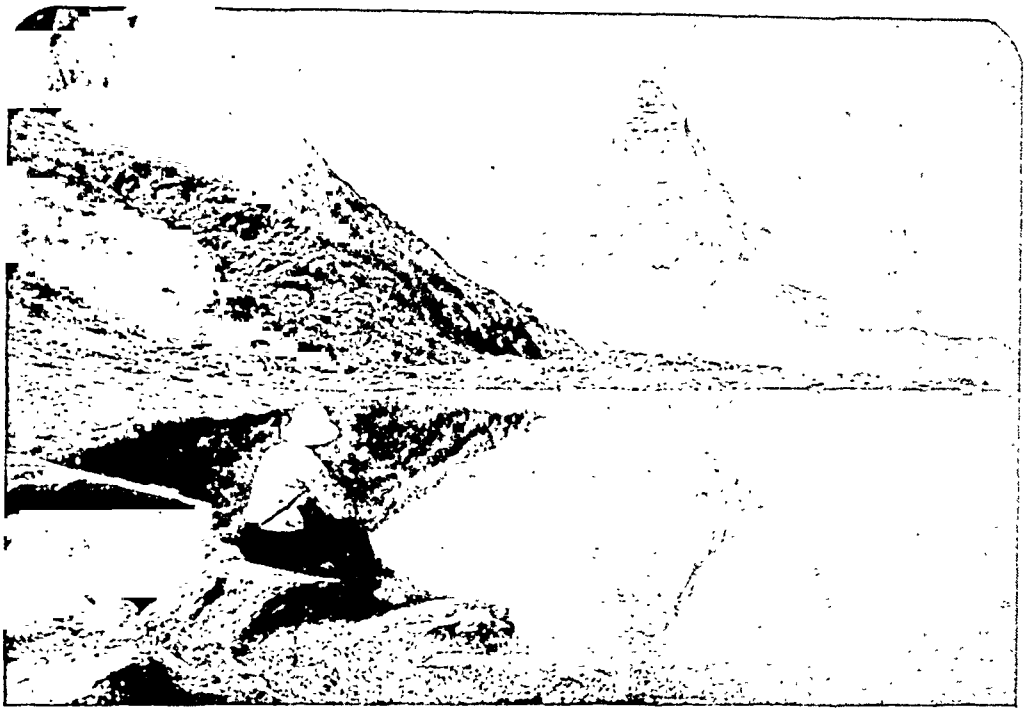
SIR,—The relation of fibro-fatty nodules to "rheumatic" syndromes, discussed by Dr. W. S. C. Copeman in his Hunterian Oration (July 23, p. 191), and the suggestion by Tegner and others (July 23, p. 201) that some rheumatic cases are of psychological origin, may distract attention from the fact that many rheumatic diseases respond favourably to manipulation and that most cases of low backache and allied diseases do so either temporarily or permanently, and are therefore probably of articular origin.

A series of 152 consecutive cases of low backache and allied diseases seen by me in the past year has yielded the following results:

Not manipulated		26
Manipulated		126
Result unknown	16	
Complete abolition of symptoms	39	
Good result with few residual symptoms	41	
Abolition of symptoms with recurrence later	25	
Manipulation failed	5	

No anaesthetic is required for this manipulation, which appears to act on the sacro-iliac joint, and is carried out as follows: (1) The patient lies on his back on the floor, with the hip and knee of the affected side each flexed to a right-angle. (2) The operator lifts the knee so that the buttock of the affected side is raised from the ground and maintains this position for a few seconds. The patient should now be free from pain. (3) The patient rolls away from the operator, who continues to lift the knee, so that the patient is lying on his sound side with the hip just clear of the ground. (4) A light blow is now delivered by the knee of the operator to the region of the greater trochanter of the affected side. In a bilateral case both sides should be manipulated.

The principle of this manipulation is that, with traction applied to the flexed and abducted hip, the innominate bone shall be driven forwards. It has been instructive to observe that the "fibrositic," neurological, psychological, and visceral symptoms present in many of these cases have abated or disappeared once the low backache has been dealt with in the manner described.—I am, etc.,



Lowestoft. N. B. EASTWOOD.

Psychogenic Rheumatism

SIR,—The article on psychogenic rheumatism by Drs. W. Tegner, D. O'Neill, and A. Kaldegg (July 23, p. 201) invites criticism. The diagnosis is in the main based on negative criteria—i.e., absence of physical signs. It is, however, clear that negative criteria are not a reliable guide to diagnosis. At the Seventh International Congress on Rheumatic Diseases at New York two Oslo physicians, Professor H. Seyffert and Dr. Monichen, expressed their conviction that the diagnosis "psychically conditioned pain is usually the indication of the doctor's inability to detect the organic cause of the pain in question." I wonder whether according to the followers of psychogenic pain the neuralgia of the fifth nerve, which has no pathology, would be considered as belonging to the same category of syndromes.

Another pertinent question is, What are the physical signs of ordinary or common "fibrositis" (non-articular rheumatism)? The diagnosis is, as a rule, based on tenderness to pressure, a subjective phenomenon which does not appear to differ very much from the tenderness due to skin hyperaesthesia which was found by the authors as "a typical reaction to examination." Or do the authors imply that every case of fibrositis is psychogenic, as maintained by Dr. J. Cyriax[1]?

In my opinion and experience psychogenic pain does not exist. In our world there is only one reality—that which exists in our minds. Hence the patient may rightly claim that the pain and sufferings he or she feels are very real indeed. I by no means deny the well-known fact that pain may be elicited or aggravated by psychological factors, but none the less it is real and somatically conditioned. There are no separate tight compartments of mind and body, which influence and depend on each other. I think it is true to say that the mind governs the body and the body governs the mind.

REFLECTION

ON SUCCESSFUL ARTIFICIAL FEEDING WITH

COW & GATE MILK FOODS

HALF CREAM

This milk food provides a most satisfactory means of introducing complementary feeding. If full artificial feeding be necessary, Half Cream ensures a minimum disturbance of infant metabolism.

FULL CREAM

The fat content approximates closely that of breast milk. Full Cream Food is prepared from finest quality milk powder made by the Cow & Gate Improved Roller Process under scientifically controlled conditions.

THESE FOODS ARE FORTIFIED BY THE ADDITION OF VITAMIN D 320 I.U. per OUNCE and IRON 1 mgm per OUNCE

** Particulars of these and other Cow & Gate preparations for specialized infant feeding will be forwarded on request.*

PLAIN TALKS ON INFANT FEEDING

No. 4

Can the infant cope with Whole Milk Protein?

Advanced opinion holds that it cannot unless that protein is reduced in quantity and character and so rendered acceptable to the child's digestion. This conversion of cow's milk into the nearest possible approximation to mother's milk, is what the makers of Trufood have achieved. Humanised Trufood is no rough and ready approximation to mother's milk. The cow's milk is broken down and reconstituted so that the nourishing factors are brought together again in the same percentages as they are found in human milk. Taking human milk as their guide, the makers of Trufood have, as it were, 'remodelled' cow's milk into breast milk. Fat, protein and carbohydrate content is practically the same in both; likewise the amino-acid composition of the proteins — a vital feature, as every doctor knows. The fat is finely emulsified as in mother's milk; and there is no hard, indigestible curd. Its calorific value is practically identical with that of mother's milk. One of the special features of Trufood is that there is no variation at any time in its character or content. Trufood costs more because more care and research must be given to its making. *Literature giving detailed information can be obtained by writing to Trufood Ltd. (Dept. BM. 44), Bebington, Wirral, Cheshire.*

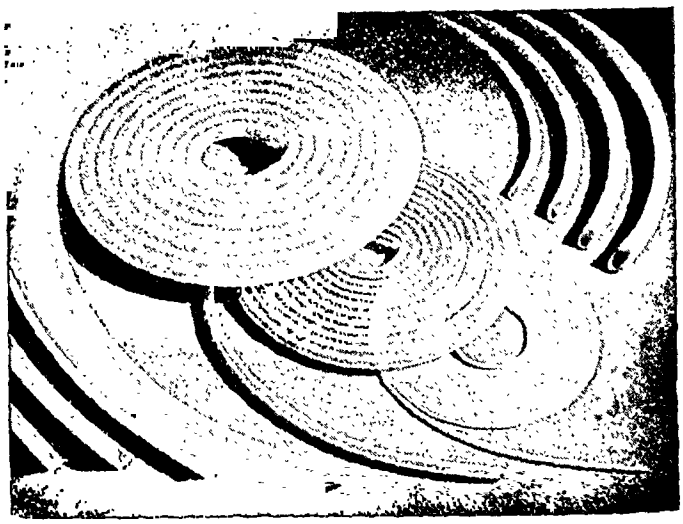
Painless INTRAMUSCULAR INJECTIONS

e.g. of PENICILLIN, LIVER EXTRACTS, ARSENO-BENZOLS, BISMUTH, etc.

Many substances create some pain on intramuscular injection. Novutox injected at the same time will prevent this pain.

Most substances are compatible with Novutox, which is also non-destructible to penicillin during the time that the latter is undergoing absorption.

Mixtures with Novutox should be made *immediately before use ONLY.*



NOVUTOX

Self-Sterilising

Local Anaesthetic

Each c.c. of Novutox 2% contains 0.02 gm. ethocaine hcl., 0.00002 gm. epinephrine and 0.00002 gm. capryl hydrocupreinotoxin hcl. Other strengths of Novutox contain these elements (with or without epinephrine) in varying proportions.

Abbey House, Victoria Street, S.W.1

According to the general theory developed by the writer[1-3] pain is due to a relatively diminished blood flow, probably by reason of pathological local vasomotor-autonomic imbalance in the affected parts. I am pretty certain that a doctor who happens to suffer from rheumatism would be very chary of diagnosing psychogenic pain *in himself*. Doctors have been accustomed to look on a patient from the point of view of diagnosis and therapy only. But I often feel it would be very useful and interesting to picture in our minds what the disease looks like when seen from the patient's viewpoint.

I have examined many a patient diagnosed as suffering from psychogenic pain, imaginary disease, etc., in whom the diagnosis of rheumatic or idiopathic myalgia could be ascertained by objective criteria and who could be relieved and helped by appropriate treatment. Why follow the deceptive will-o'-the-wisp of psychogenic rheumatism, imaginary disease, or the conception of "fibro-fatty tissue" in new rheumatic syndromes if the modern methods allow us to ascertain or exclude rheumatic myalgia with certainty by objective criteria? The apparently new fashion of coining and describing more and more syndromes has already led to confusion in rheumatism. It is time, I think, to return to a unitary disease—i.e., rheumatic myopathy—responsible for non-articular and articular rheumatism. It seems certain that in science progress depends largely on simplification of terms and conceptions.—I am, etc.,

London, N.W.11. M. G. GOOD.

Conceptions of Right and Wrong

SIR,—Dr. Frederick Dillon (August 27, p. 485) seems to have been somewhat misled as to the degree of "guilty knowledge" (*mens rea*) inferred by the word "wrong" as used in the M'Naghten rules, and has come to the unhappy conclusion that as a result of the reference made by Sir Hartley Shawcross to it in the recent Haigh trial it has been given two distinct interpretations. This is not so.

The rule as to criminal liability of persons afflicted with insane delusions is based on the answers of the judges given to the House of Lords extra-judicially in consequence of M'Naghten's case in 1843. One of these answers (the first) accounts for the question put by Sir Hartley in Haigh's case. "The party accused . . . is punishable according to the nature of the crime committed, if he knew at the time of committing such crime that he was acting contrary to law" (i.e., the law of the land).

Let us now pass to the third answer given by the judges, which clearly deals with the point upon which your correspondent appears to be a little confused. " . . . To establish a defence on the ground of insanity it must be clearly proved that at the time of committing the act the party accused was labouring under such a defect of reason, from disease of the mind, as not to know the nature and quality of the act he was doing (this refers to the physical character alone), or, if he did know it, that he did not know he was doing what was wrong. The mode of putting the latter part of the question to the jury on these occasions has generally been whether the accused at the time of doing the act knew the difference between right and wrong, which mode, though rarely if ever leading to a mistake with the jury, is not as we conceive so accurate when just put generally and in the abstract as when put as to the party's knowledge of right and wrong in respect of the very act with which he is charged. If the question were to be put as to the knowledge of the accused solely and exclusively with reference to the law of the land it might tend to confound the jury by inducing them to believe that an actual knowledge of the law of the land was essential in order to lead to a conviction, whereas the law is administered upon the principle that everyone must be taken conclusively to know it without proof that he does know it. If the accused was conscious that the act was one which he ought not to do, and if that act was at the same time contrary to the law, he is punishable; and the usual course, therefore, has been to leave the question to the jury whether the party accused had a sufficient degree of reason to know that he was doing an act that was wrong."

I think this will afford the authoritative explanation of the meaning of the word "wrong" which Dr. Dillon requires.

Sir Hartley Shawcross at the Haigh trial referred to the word "wrong" in its strict sense as being contrary to the law of the land. It is, however, sufficient that the accused is capable of distinguishing between right and wrong, *irrespective of* whether he appreciates that the "wrong" amounts to a criminal offence, for *ignorantia legis excusat neminem*.

The point is, did the accused at the time he committed the act know that he was doing something which was wrong? The fact that it should also amount to a crime is the reason why he is before the court and the M'Naghten rules are applied at all. If it was merely an act which was morally wrong but not contrary to the law of the land, then these rules could have no application, for the question of criminal proceedings would not arise.—I am, etc.,

Lincoln. J. E. WILSON.

Paddington Green Children's Hospital

SIR,—The Paddington Green Children's Hospital is to be closed down. I think that this news should be widely spread, and I ask you to allow me to give my personal view of this, which I consider to be a tragedy.

The following general facts should be advertised, if only that they can be corrected if wrongly stated. After the war the idea was spread around that the small hospitals would not survive unless they got under the wing of larger institutions. Reluctantly, Paddington Green allowed itself to be taken over by St. Mary's, with which teaching hospital it had always been on the friendliest terms. Since it was taken over there has been a happy experience of co-operation between the parent and the adopted child. Subsequently St. Mary's took over other hospitals, including the Princess Louise Hospital for Children.

Suddenly the St. Mary's Hospital Board announced its intention of destroying Paddington Green and of using its walls as the basis for a new wing for the care of adult skin and throat cases. In the printed statement (marked "confidential" for some reason not given) it is made clear that regional needs are not under consideration, but only the needs of St. Mary's as an undergraduate teaching hospital. Apparently someone at St. Mary's has blundered, and more children's beds have been taken over than are specified as minimum requirements in the Goodenough Report. The board's way out is to destroy one of the two children's hospitals adopted and so make the numbers of skin and throat beds add up nicely. No mention is made of out-patient and casualty needs.

This state of affairs must surely interest the profession and also the general public. The teaching of medical students is apparently a matter of compliance with the Goodenough recommendations, and it is not a matter of letting students feel that the direct needs of the public are also important.

It is not for us to praise our own hospital, but who will defend it if we do not do so? I personally think that mothers and children get excellent service at Paddington Green, and 39,000 mothers bring their children to the hospital every year. No alternative provision whatever is to be made for these mothers. Certainly these 78,000 persons (mothers and children) cannot be wanted in the terribly overcrowded out-patient department at St. Mary's.

As my specialty is towards the psychological side, I can perhaps say that the physical paediatrics practised by my colleagues is as good as any. Moreover, the parents and children are treated as human beings. Any children's hospital is a very specialized affair. The matron, the nurses, the dispenser, the almoner, the telephone girl are all there because mothers and children interest them. The special departments are adapted to the handling of parents and children. Such an institution cannot be created suddenly. Paddington Green has been 80 years in the making. Many of the parents came to the hospital when they were children themselves. Locally, a children's hospital has a value even when it is not used, as a

place that is known and that can be used in case of doubt or emergency.

It seems to me that it is a disgrace and a very irresponsible thing that a teaching hospital board should come to a decision like this without reference to local out-patient needs. I feel that if the scheme is carried through the reputation of St. Mary's will suffer for a long time, both locally and generally in the profession.

I am near enough to the end of my service to Paddington Green to be able to publish my personal view without its being thought that I am just annoyed about my personal loss. As a matter of fact I do feel annoyed and insulted—in fact, we have all been stunned. This was one of those things that could not happen, the destruction of a good thing and for a paltry reason.

There seems to be no way of getting this matter brought into the open except in your invaluable correspondence columns.—I am, etc.,

London, W.1. D. W. WINNICOTT.

Princess Tsahai Memorial Hospital

SIR,—May I ask for the hospitality of your columns to inform your readers that the building of the Princess Tsahai Memorial Hospital in Addis Ababa is now complete : 85% of the necessary £100,000 has been raised, and two-thirds of the interior equipment has been shipped. The appeal committee wishes to order the remaining equipment, and I appeal strongly to the generous British public to assist in raising the £15,000 still necessary to bring this worthy project to fulfilment. High hopes have been raised of services to be rendered by the hospital, more especially because it will be feasible to attach to it a nursing and midwives' training school (for which funds are in sight) and eventually a medical school.

The late Princess Tsahai was a noble-spirited girl who died at 23 after giving five years' devoted service in British hospitals during the late world war. One of her matrons wrote that she possessed "patience, loyalty, gentleness"; another described her as "gentle and dignified." Her father, the Emperor Haile Selassie, earned respect and admiration for his courage and bearing from all who met him in his days of adversity. His interest is deeply engaged in seeing the hospital at work.

Cheques and postal orders will be very gratefully received by the honorary treasurers of the appeal committee, Lord Horder and Lord Amulree. They should be drawn in favour of the Princess Tsahai Memorial Hospital and sent to the honorary treasurers, care of Messrs. Gould and Prideaux, the honorary accountants, at 88, Bishopsgate, London, E.C.2.—I am, etc.,

House of Lords WINSTER.

POINTS FROM LETTERS

Marking Gas Cylinders

Mr. K. C. WARD (Loughborough) writes: It is strange that no one has yet found a simple expedient for the distinguishing of gas cylinders that could be adopted universally. Surely it would not be too big a drain on the financial resources of the National Health scheme for the Minister to provide every hospital with a supply of paint transfers. One of the pharmaceutical staff could then be responsible for marking each cylinder by means of the transfers with the name of the contents, and this would ensure that even though the paint round the neck of the cylinder was chipped, destroying any easily visible marking, some alternative means of ready identification would be there. It really is distressing to read of these by no means uncommon fatalities due to confusion of gas cylinders.

Anterior Poliomyelitis and Herpes Zoster

Dr. COLIN GRAHAME (Boreham Street, Sussex) writes: Some features of similarity in these two diseases should be worthy of consideration at the present time. Although it is said the viruses of the two affections are distinct, it would be interesting to learn if herpes zoster has become more common during the last 30 years. I am of the opinion that some points of similarity are sufficiently significant to suggest that herpes zoster should be a notifiable disease, at least temporarily until statistical records could be compared. . . . The vanguard of success in mastering anterior poliomyelitis is still observation, and its association in relation to other diseases is very important. It is also time that the designation of infantile paralysis was discarded for that of "infectious paralysis."

Obituary

H. H. MOLL, M.D., F.R.C.P.

Dr. Henry Moll, senior physician to the United Leeds Hospital, died suddenly at Leeds on September 8 at the early age of 53. He was born in Milan in 1896. His father, who lives in Milan, was born in Lyons, and his mother, who died young, belonged to a Scottish family which for several generations has divided its life between Edinburgh and Leghorn.

Henry Henderson Moll received his early education in the Lyceum at Milan, and he began his medical course in the University of Pavia. His studies were interrupted by the first world war, in which he served as a medical student, with the rank of sergeant. He concluded his medical studies in Rome and obtained the M.D. of this university with the highest honours. He came to England in 1920 and immediately applied himself to intensive study at St. Bartholomew's Hospital and at the West London Hospital. Dr. Moll came to Leeds in 1922 as a resident officer at the General Infirmary, Leeds.

He took the Leeds M.B., Ch.B. in 1925. His breadth of experience and great industry were soon recognized, and he was appointed an assistant physician to the hospital. By the time of his tragically early death he had reached the highest position on the medical staff of the General Infirmary. Throughout the war he worked at the Pinderfields Emergency Hospital at Wakefield. He remained on the staff of this hospital, and at the time of his death he was absorbed in the creation of a hospital school for asthmatic children there.

Dr. Moll preserved throughout his professional life a great interest in asthma and diseases of the chest. He wrote an important study on bronchiectasis, which has been often quoted. He was in charge of an asthma clinic and research unit for many years at the General Infirmary, Leeds, and he was an advisory member of the Asthma Research Council. His great interest in allergy found expression in the support he gave to the newly founded British Association of Allergists; shortly before his death he attended a general meeting of this association at Cardiff and made a valuable contribution to a discussion on the treatment of bronchial asthma. On this occasion he was invited to allow his name to go forward for election as a member of the council of the association. Dr. Moll will be remembered by generations of students of the Leeds School as a fine teacher, careful in preparation, precise and sometimes a little dogmatic in the presentation of his theme. Students remembered what Dr. Moll had told them and always found it possible to apply this knowledge in practice. Moll himself was a fine embodiment in our own times of the practice of past centuries when there was an interchange between English universities and the classical universities of Italy, the oldest in Europe.

A reserved person who became for those who knew him a most warm and genial spirit, Dr. Moll's courtesy and

gentleness were graces which his friends will never forget. His interests outside medicine were in music and painting, and nothing gave him more delight than the work of Cesca, his wife, an artist of distinction. He was devoted to his family. To his wife and four children, the eldest of whom is 12, the sympathy of all who knew him will be extended.—G.W.B.

JOHN GERRIE, F.R.C.S.Ed.

Mr. John Gerrie died suddenly on July 4, in Harrogate, while attending the Annual Meeting of the British Medical Association. The announcement of his unexpected death at the early age of 41 seemed almost incredible, for with his burly and robust figure he seemed the embodiment of health and fitness. An Aberdonian by birth, he was educated at Robert Gordon's College and graduated M.B., Ch.B. with honours at the University of Aberdeen in 1930. His undergraduate career was a distinguished one, and he was awarded many medals and prizes, particularly in the field of surgery. Immediately after graduation he was for a time assistant in the department of anatomy under Professor Alexander Low, thus laying a secure foundation for the specialty to which he was later to devote himself, and acquiring a training in morphology and embryology which was reflected in his later published work. There followed a series of resident hospital appointments at Queen Mary's Hospital, Stratford, at the Central London Throat Hospital, and at the Manchester Ear Hospital. Although his bent was already towards otolaryngology, he wisely decided to spend some time in general practice, and for some three or four years he practised in partnership in Greenwich. In 1934 Gerrie obtained the F.R.C.S.Ed., and shortly afterwards he was appointed assistant surgeon in the ear, nose, and throat department of Aberdeen Royal Infirmary. In addition he held appointments at the Royal Aberdeen Hospital for Sick Children and at the municipal hospitals. He rapidly built up an extensive practice, and some three years ago he became full surgeon in charge of his department and was appointed lecturer in diseases of the ear, nose, and throat in the university. During the war years his work was extremely onerous and taxed his strength severely, and not until the end of the war was he able to resume his research work.

By his medical colleagues, by his students, and by his patients John Gerrie will be remembered not merely for his skill in his specialty but perhaps still more for his sterling qualities as a man—for his friendliness, his sense of humour, and above all for his kindness. From his experience in general practice he had learned much, and in his work he spared himself neither time nor trouble to ensure the comfort, both mental and physical, of his patients, and especially of young children. This quality was very clearly seen in one of the earliest papers which he published on basal narcosis for tonsillectomy in children. To this problem he gave much time and thought in an endeavour, happily successful, to make the operation of tonsillectomy in children less of an ordeal to the small patient. Perhaps his most important paper was that on the phylogeny of the mammalian tympanic cavity and auditory ossicles, published in 1948, in which the influence of his earlier anatomical training comes out clearly, and which forms a valuable contribution to our understanding of the tympanic cavity and its development. In his scanty leisure his main interests and hobbies were in art and music, in the former of which he had considerable talent, as shown by the fact that the illustrations in the paper referred to above were from his own drawings.

His students, with whom he was on the friendliest terms, have placed on record a few sentences from one of his own lectures which exemplify his attitude to his life and to his work: "To win a child's confidence is half the battle. One must come down to its level—no difficult thing for me." Therein lay his success, for to the end of his tragically short life he retained a certain quality of boyishness which was one of his most engaging qualities and to which children instinctively responded. He could become one of them without side, self-consciousness, or condescension. In his relations with his hospital colleagues Gerrie was equally happy. In many ways he was typical of the land in which he was bred and of the university in which he was trained, for with few initial advantages he had made his way in his profession by dint of his conscientiousness, his natural ability, and his capacity for sustained work.

His life was summed up in his home and in his work, in both of which he was supremely happy. Only two years ago one remembered the joy and happiness of his wife and himself in the birth of their twin children—a son and a daughter. To his widow and his young family the sincere sympathy of his many friends and colleagues is extended in full measure.—A.G.A.

DR. ANNIE DOROTHEA SYMONS died suddenly on August 18 at her home in Bournemouth at the age of 59. She intended to be a medical missionary, and her fees at the Royal Free Hospital, where she qualified in 1924, were paid by a missionary society. However, after qualifying she was never fit enough to pass the necessary medical examination. She went to Bridgwater General Hospital as a house-surgeon, and later she took over a practice which became vacant in Bournemouth. Working from a small, noisy house on the main road in Boscombe, she built up a very large practice. Dr. Symons had great personal charm, keen intuition, and clinical insight, and she won the affection and confidence of all. Her acts of kindness to her patients extended far beyond her medical obligations. In March, 1948, Dr. Symons had a serious operation and knew that there was no hope of recovery. She was never able to return to full work, but did all that her strength would allow right up to the end. Her calm acceptance of the position and her courage, humour, confidence, and happiness in the last days of acute physical distress were an inspiration to her colleagues and friends.

Universities and Colleges

UNIVERSITY OF BIRMINGHAM

The opening ceremony of the new session of the Faculty of Medicine will take place in the Nurses' Recreation Hall, Nuffield House, Queen Elizabeth Hospital, on Tuesday, October 4, at 3 p.m., when the Lord Archbishop of Canterbury, P.C., D.D., D.L., will distribute the prizes awarded for the session 1948–9 and deliver an address to students. Past and present members of the Medical School are invited to attend, and tickets may be obtained from the Sub-Dean, the Medical School, Birmingham, 15.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At a meeting of the Royal Faculty of Physicians and Surgeons of Glasgow held on September 5, with Dr. W. R. Snodgrass, president, in the chair, the following candidates were admitted Fellows of Faculty *qua* Physician: J. B. Barr, A. J. MacK. Campbell, R. Fife, W. M. Fyfe, S. C. Ghosh, J. T. Hutchison, A. C. Kennedy, A. W. Lees, R. F. Maggs, A. G. Melrose, G. A. V. Ribeiro, Irene P. Rowlands, R. S. Singh, T. J. Thomson, G. F. Walker. The following were admitted Fellows of Faculty *qua* Surgeon: A. El H. Bayoumi, A. K. Brown, H. McC. Carson, G. A. Clark, H. B. Crum, F. G. Day, J. S. F. Hutchison, J. Lockie, I. R. McCaul, J. R. Macintyre, A. Mellick, P. S. Olivier, F. Riggall, P. L. Rishi, D. J. Toomey, W. F. Toomey, H. B. Watson.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended September 3. [No. 35

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

‖ Includes puerperal fever for England and Wales and Eire.

EPIDEMIOLOGICAL NOTES

Typhus Fever in a Ship

The s.s. *Monte Montjuich* arrived in the Port of London from Melilla (North Africa) on August 17. On August 22 two members of the crew were admitted to hospital with suspected enteric fever, and a third on August 25. The vessel then sailed for Newport (Monmouth) and arrived on August 28. A fourth member of the crew was sent to hospital on arrival with a similar diagnosis. Two further similar cases occurred on September 6, while another member was under treatment in hospital for middle-ear disease.

All the usual sanitary measures were taken on board, and in addition fumigation was carried out in Newport, when 805 rats were destroyed. The ship sailed for Rosario, Argentina, on September 7.

Laboratory tests on these cases proved negative until September 2, when Widal tests on the first two patients suggested a paratyphoid B infection. On September 7, however, a repetition of the Weil-Felix tests on serum from the seven patients were found to be positive for typhus infections, but further investigation on board was not possible, as the ship had sailed that morning. All the patients are recovering, and the attack was a mild one in every case. There was no evidence of lice infestation.

It is not yet apparent whether the infection was of murine or louse-borne origin, and further work is in progress on this point. All seven patients were removed to isolation, and the disease has remained confined to members of the crew of the ship. Spread in the British Isles is not expected.

Food-poisoning in North Staffordshire

An outbreak of food-poisoning occurred in a semi-urban area in North Staffordshire on August 31 and September 1. All the 40 cases notified were adults, and all reported that they had eaten brawn prepared and retailed by a local butcher. Cases were strictly confined to houses where brawn had been consumed; persons who had eaten the brawn were the only ones to be affected; no further cases occurred after the brawn had been withdrawn from sale. From the amount of brawn sold it was estimated that the number of persons at risk was 100 to 150.

The time between ingestion and onset of illness in all cases was from two and a half to three hours. The main symptoms were nausea, vomiting, and abdominal pain followed by diarrhoea. In a few cases the pain was reported to be severe. Several patients were said to have "collapsed," and of these two old people became dangerously ill. Cyanosis of the lips was reported among the more severely affected cases. Recovery seems to have been practically complete within 48 hours. There were no deaths.

Samples of the brawn were obtained from the butcher's shop and from two households; all proved to be heavily contaminated by coagulase-positive *Staphylococcus aureus*. The faeces of three severely affected patients showed no pathogenic organisms. A swab taken from a small boil, from which pus could be expressed, on the butcher's right hand yielded a pure culture of coagulase-positive *Staphylococcus aureus*. Cultures of staphylococci obtained from the brawn and from the pustule on the butcher's hand were sent to a reference laboratory for bacteriophage investigation, and they were characterized as "untypable."

There seems to be little doubt that the cause of the outbreak was staphylococcal enterotoxin, and in the light of various factors it seems clear that contamination occurred after the process of cooking. Although it cannot be definitely stated that the contamination of the brawn was caused by organisms from the pustule on the butcher's hand, the possibility remains and provides another instance of what appears to be a fairly common cause of such outbreaks.

Poliomyelitis

Notifications in England and Wales in the week ended September 10 were: poliomyelitis 284 (289), polio-encephalitis

22 (19). Figures for the previous week are shown in parentheses.

Multiple cases (poliomyelitis and polio-encephalitis together) were reported from the following counties: London 31 (43), Berkshire 4 (5), Chester 6 (3), Cornwall 3 (5), Derby 2 (2), Devon 5 (7), Dorset 5 (2), *Durham 7 (8), Essex 16 (21),* Gloucester 10 (13), Hereford 2 (10), Hertford 5 (3), Kent 9 (10), Lancaster 38 (28), Leicester 7 (11), Lincs, Kesteven 2 (2), Middlesex 19 (18), Northumberland 8 (10), Nottingham 16 (6), Oxford 4 (1), Soke of Peterborough 5 (0), Somerset 5 (9), *Southampton 15 (10), Stafford 4 (3), Surrey 9 (7), Sussex E.* 4 (2), Warwick 10 (8), I. of Wight 2 (0), Wiltshire 8 (4), Yorks East Riding 3 (1), Yorks West Riding 25 (37), Glamorgan 7 (5), Monmouth 2 (1).

Notifications in England and Wales in the corresponding week of 1947 (*week ended September 6*) were: *poliomyelitis* 662, polio-encephalitis 46. These were the highest weekly figures recorded in that year.

Discussion of Table

In *England and Wales* the only large variations in the returns of infectious diseases were an increase of 31 in the notifications of acute poliomyelitis and decreases in the incidence of measles 610 and whooping-cough 56.

A fall in the incidence of measles was general throughout the country; the largest decrease was 62 in Durham. The only fluctuations of note in the local incidence of whooping-cough were decreases in Warwickshire 50 and Durham 28, with an increase of 24 in Lancashire.

The incidence of scarlet fever remained constant in most areas, the only large variation in trend being an increase of 24 in Lancashire. Notifications of diphtheria were only one more than the record low level of the preceding week.

Fresh outbreaks of dysentery were notified in Yorkshire, Leeds C.B. 31, and Northumberland, Gosforth U.D. 21. Only one further case of dysentery was recorded in Staffordshire, Wolverhampton C.B., where 29 cases were notified in the preceding week. Of the 30 cases of paratyphoid fever 17 were notified in Lancashire (Liverpool C.B. 8). The largest outbreaks of food-poisoning were: Staffordshire (Newcastle-under-Lyme R.D. 38 (see above)). Lancashire (Blackpool C.B. 25, Liverpool C.B. 13, Farnworth M.B. 10), Surrey (Croydon C.B. 18), Kent (Margate M.B. 16), and Northumberland (Wallsend M.B. 14).

In *Scotland* a decrease of 36 in the notifications of measles and an increase of 26 for acute primary pneumonia were the only appreciable fluctuations in the totals for the week. In Glasgow 52 cases of dysentery were notified, an increase of 6. The increase in the incidence of pneumonia was mainly contributed by Glasgow. Only two areas returned notifications of acute poliomyelitis, Edinburgh 3 and Glasgow 8.

In *Eire* notifications of diarrhoea and enteritis rose from 74 to 159; the largest returns were Dublin C.B. 119 and Cork C.B. 18. Notifications of scarlet fever were 29 more than in the preceding week due to a general rise in incidence.

In *Northern Ireland* the chief feature of the returns was a decrease of 21 in the notifications of measles. Of the 7 cases of diphtheria 5 were notified in Co. Antrim.

Week Ending September 10

Notifications of infectious diseases in England and Wales during the week included: scarlet fever 729, whooping-cough 1,228, diphtheria 66, measles 875, acute pneumonia 205, cerebro-spinal fever 38, acute poliomyelitis 284, acute polio-encephalitis 22, dysentery 59, paratyphoid fever 20, typhoid fever 3, food-poisoning 212.

The Ministry of Health has asked hospitals to minimize the consumption of electricity during the peak hours in the coming winter, with the object of spreading the load. The consumption of electricity should be restricted from 8 a.m. to 9.30 a.m. on Mondays to Fridays from October 1, 1949, to March 31, 1950, and from 4 p.m. to 5.30 p.m. on Mondays to Fridays from November 1, 1949, to January 15, 1950.

Medical News

New Members of M.R.C.

By an Order of the Committee of Privy Council for Medical Research, made after consultation with the Medical Research Council and with the president of the Royal Society, the following have been appointed to be members of the Medical Research Council from October 1, 1949: Dr. N. Hamilton Fairley, F.R.S., Sir Percival Hartley, F.R.S., and Professor J. McMichael, F.R.C.P.

Register of Hydrotherapy Assistants

The Chartered Society of Physiotherapy has decided that in order to ensure a satisfactory standard of treatment in hydrotherapy establishments and in order to bring this class of worker under the aegis of the chartered society as the responsible professional body, it will make itself responsible for the training and registration of persons carrying out, or assisting in carrying out, certain hydrotherapeutic treatments at hydrotherapy establishments throughout the country. The council of the chartered society has therefore agreed to inaugurate a scheme of training leading to examination and registration on a "Supplementary Register of Hydrotherapy Assistants" to be maintained by the chartered society.

Christmas Cards

The Grenfell Association has again prepared a series of Christmas cards depicting typical scenes in Labrador and in Northern Newfoundland where its medical work continues. Profits from the sale of these cards will help to maintain hospital and nursing stations, and will also be applied to the campaign against tuberculosis, which is one of the most serious problems in this part of the world. Some of the cards are in black and white, and others are in colour. An illustrated leaflet showing the kinds of cards available and their prices can be obtained (price 1d.) from the secretary, the Grenfell Association, 66, Victoria Street, London, S.W.1.

Buckston Browne Prize Essay

The council of the Harveian Society of London has selected "*The Management of the 'Hopeless' Case*" as the subject for the Buckston Browne prize essay. The prize, consisting of a medal, together with the sum of £100, will be awarded for the best essay on the subject; is open to any member of the medical profession registered in the British Isles or Dominions; and is limited to candidates under 45 years of age. Essays must be sent in by October 1, 1950. Further particulars may be obtained from Sir Cecil Wakeley, P.R.C.S., 73, Portland Place, London, W.1.

Wills

Dr. Donald George Hall, of Hove, left £41,711, including £500 to the Medical Benevolent Fund. Dr. Alfred Heathcote Copeman, also of Hove, left £39,212; Dr. James Robertson Wills, of Peterborough, left £12,342; Dr. David Riddell, of Windermere, formerly High Sheriff of Westmorland, £37.829; Dr. Samuel Morris Green, of Prescot, Lancs, £13,442.

COMING EVENTS

Royal Free Hospital School of Medicine

The inaugural address for the 1949–50 session of the Royal Free Hospital School of Medicine will be delivered by Mr. James Laver, Hon.R.E., at B.M.A. House, Tavistock Square, London, W.C., on Friday, September 30, at 3 p.m. His subject is "Clothes and Psychic Health."

Conference on Foot Inspection

A conference on "Foot Inspection in *Childhood* and Adolescence" has been arranged by the Foot Health Educational Bureau, to be held at Caxton Hall, Westminster, London, S.W., on Friday, September 30, from 2.15 to 5 p.m. The speakers will be Dr. W. G. Booth and Mr. T. T. Stamm.

Conference on Juvenile Delinquency

A Conference on the Scientific Study of Juvenile Delinquency will be held at the Royal Institution, 21, Albemarle Street, W., on Saturday, October 1. The conference was convened by the British Psychological Society, the Howard League for Penal Reform, the Institute for the Scientific Treatment of Delinquency, the Institute of Sociology, the National Association for Mental Health, and the Royal Medico-Psychological Association. The Earl of Feversham will open the meeting, which will be divided into morning and afternoon sessions. In the morning a discussion will be held on the limits of present knowledge, under the chairmanship of Mr. J. C. Maude, Recorder of Plymouth. The speakers will include Dr. J. D. W. Pearce and Dr. Hermann Mannheim. In the afternoon Miss Margery Fry will take the chair in a discussion on future research. Dr. John Bowlby and Dr. Dennis Carroll will be among the speakers.

Exhibition of Medical Photography

The Exhibition of Medical Photography organized by the Medical Group of the Royal Photographic Society of Great Britain is to be shown in the Museum, Manchester Royal Infirmary, from Monday, October 3, to Saturday, October 8. The exhibition will be open from 9 a.m. to 6 p.m. daily, and on Saturday until 1 p.m.

Postgraduate Lectures in Ophthalmology

A series of postgraduate lectures in ophthalmology will be given in the Department of Ophthalmology of the University of Glasgow on Wednesdays, October 5, 12, 19, and 26, at 8 p.m. A discussion will follow each paper. The meetings are open to all medical practitioners and senior students interested in the subject. Details will be published in the *Journal* under "Societies and Lectures" week by week.

Welsh National School of Medicine

Dr. W. N. Pickles is delivering the annual inaugural address to the Welsh National School of Medicine on October 6. His subject is "Epidemiology in Country Practice."

Charing Cross Hospital Medical School

The inaugural address will be given by the Rt. Hon. Sir Norman Birkett, M.A., LL.B., in the council room of the hospital on Thursday, October 6, at 4 p.m. The prizes will be presented by Lady Birkett. The medical school will be open for inspection from 2 to 3.30 p.m.

Kettle Memorial Trust Lecture

The Fifth Kettle Memorial Trust Lecture will be delivered by Dr. Beatrice Pullinger at the Royal College of Surgeons of England (Lincoln's Inn Fields, London, W.C.), on Friday, October 7, at 5 p.m. Her subject is "The Significance of Functional Differentiation in Mammary Tumours."

Prevention of Accidents

A conference organized on behalf of the Association of British Chemical Manufacturers by the Royal Society for the Prevention of Accidents will be held at the Royal Hotel, Scarborough, on October 7–9. Among subjects to be discussed are the safe use of solvents, the installation and maintenance of breathing apparatus, and the use of electric apparatus in hazardous atmospheres. The fee for the conference, including accommodation, is £5. Particulars can be obtained from the Royal Society for the Prevention of Accidents, Industrial Safety Division, 131, Sloane Street, London, S.W.1.

Medical Golf

The Furness Division of the British Medical Association has arranged another golf tournament to be held at Grange Golf Club on Sunday, October 9, at 2.15 p.m. It is hoped that all members who participated in the previous one at Ulverston will again enter for this competition, and that any other member of the Division who plays golf will also enter. Names should be forwarded to the honorary secretary of the Furness Division, Dr. J. Mitchell Stuart, c/o the Clinic, Vickers-Armstrongs, Ltd., Naval Construction Works, Barrow-in-Furness, by September 26, so that arrangements may be completed.

Industrial Nursing

The Royal College of Nursing will hold a conference on "The Industrial Nursing Service" on October 7–8 at the Royal College, Henrietta Place, Cavendish Square, London, W.1. Those requiring tickets should apply as soon as possible to the Conference Secretary at the address above.

SOCIETIES AND LECTURES

Tuesday

INSTITUTE OF SOCIOLOGY.—At Royal Society, Burlington House, London, W., September 27, 5.30 p.m., discussion meeting jointly with British Society for the History of Science, "*Goethe and Modern Thought*," by Mr. Humphry Trevelyan. Professor William Rose will open the discussion.

Friday

CAMBRIDGE MEDICAL SOCIETY.—At Addenbrooke's Hospital, Cambridge, September 30, 2.30 p.m., "*Meddlesome Midwifery*," talk by Miss Janet Bottomley.

APPOINTMENTS

Dr. Isabel G. H. Wilson has been appointed a Senior Commissioner and Member of the Board of Control on the retirement of Miss Ruth Darwin.

Dr. Wilson graduated at Edinburgh in 1921, took the D.P.M. in 1924, and proceeded M.D. in 1926. She was elected F.R.C.P. in 1947. In 1938 she prepared jointly for the Board of Control a report on cardiazol treatment and hypoglycaemic shock treatment in schizophrenia.

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—*Consultant Physician for Mental Deficiency in Western Part of East Anglian Region*, W. Sharp, M.B., Ch.B., D.P.M. *Consultant Psychiatrist for Child Guidance Services in the Ipswich Area*, J. G. Howells, M.B., B.S., D.P.M.

SOUTH WESTERN REGIONAL HOSPITAL BOARD.—The following appointments have been announced: *Director, Rheumatism Unit and Advisor on the Service—South Western and Oxford Regional Boards*, G. D. Kersley, M.D., F.R.C.P. *Surgeon, South Devon and East Cornwall Hospital, Plymouth*, J. P. Childs, M.Ch., F.R.C.S. *Anaesthetist, Neurosurgery Department, Frenchay Hospital, Bristol*, P. L. F. Mortimer, M.B., B.S., D.A. *Assistant Dental Surgeon, Plastic Surgery Department, City General Hospital, Gloucester*, H. Handley, B.D.S. *Medical Director, Mass Radiography Unit, Plymouth*, G. Sheers, M.B., B.Chir. *Physician-Superintendent, Quantock Sanatorium, Somerset*, B. J. Douglas Smith, M.B., B.S.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Ferguson.—On August 29, 1949, at Birch Hill Hospital, Rochdale, to Eileen (née O'Brien), wife of Dr. T. I. V. Ferguson, a son.

Gidley.—On September 4, 1949, at Manor Hospital, Nuneaton, to Maisie (née Merry), M.B., B.S., D.A., a son—Alexander Claude.

Graves.—On September 13, 1949, to Valerie (née Scotland, M.B., B.S.), wife of Dr. J. C. Graves, 9, Westgate Avenue, Holcombe Brook, Lancs, a daughter.

Rose.—On September 9, 1949, at 80, Harborne Road, Birmingham, 32, to Dr. Mary Rose (née Lavender), wife of G. K. Rose, F.R.C.S., a son—Robert Ewart.

MARRIAGES

Daniel—Williams.—On August 27, 1949, at Cwmtwrch, Owen Daniel, M.B., F.R.C.S., of Glanamman, Carms, to Rhianydd Williams, of Cwmtwrch, Breconshire.

Davidson—Fortune.—On August 29, 1949, at Caxton Hall, Westminster, John Howard Davidson, M.B., B.S., to Phylis Mary Veronica Fortune.

Protheroe Smith—Fletcher.—On September 13, 1949, Edward Protheroe Smith, M.R.C.S., L.R.C.P. (late of Redditch), to Margaret, daughter of the late Mr. and Mrs. T. W. Fletcher, of Webheath, Worcs.

DEATHS

Bickerton.—On September 13, 1949, at 33, Portland Place, London, W., Reginald Ernest Bickerton, D.S.O., M.B., Ch.B., Colonel R.A.M.C., T.A.

Elworthy.—On September 11, 1949, Reginald Robert Elworthy, O.B.E., M.D., of 18, St. Margaret's Drive, East Twickenham, Middlesex.

James.—On September 12, 1949, Edmund Arnold James, M.B., Ch.B., of Trencrom, St. Helen's Place, Castleford, Yorks.

Jenkins.—On September 15, 1949, Charles Evans Jenkins, M.R.C.S., L.R.C.P., of Dunedin, Sale, Cheshire.

Kinloch.—On September 14, 1949, at 305, Upper Shoreham Road, Shoreham-by-Sea, Sussex, William Anderson Kinloch, M.B., C.M., aged 76.

Macdonald.—On September 10, 1949, at Lynton, Thrupp Lane, near Stroud, Glos, Alexander Tulloh Inglis Macdonald, M.D., formerly of Bootle, Liverpool.

Mannington.—On September 12, 1949, at Hillbrow, 49, St. Helen's Crescent, Hastings, Sussex, Frank Mannington, F.R.C.S., formerly of Muswell Hill, London, N., aged 75.

Munro.—On September 18, 1949, at Beech House, Egremont, Cumberland, James Gibson Munro, M.B., Ch.B.

Rowand.—On September 15, 1949, at a nursing-home, St. Andrews, Andrew Rowand, M.D., formerly of 19, Queen's Gardens, St. Andrews, aged 86.

Sanders.—On September 16, 1949, Ernest Leonard Sanders, M.B., Ch.B., of 122, Lauriston Place, Edinburgh, 3.

Smith.—On September 16, 1949, at Mount Vernon Hospital, Harry Smith, M.R.C.S., L.R.C.P., D.P.H., of Sunnyways, Gerrards Cross, Bucks.

Smyth.—On September 11, 1949, at Four Walls, Formby, Lancs, John Francis Smyth, M.D., D.P.M.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Streptococcus Viridans and Bacterial Endocarditis

Q.—*Is there any evidence that the Streptococcus viridans found in the mouth and throat is the same as that found in a case of bacterial endocarditis?*

A.—The evidence that the *Streptococcus viridans* found normally in the mouth and throat is the infecting organism in subacute bacterial endocarditis is largely circumstantial. Gum sepsis, including periodontal abscess, is most often due to infection with non-haemolytic streptococci of the *viridans* and *salivarius* types. Any trauma of an infected gum, such as by tooth extraction, usually results in a temporary bacteriaemia, and if there are damaged heart valves, due to congenital defect or previous rheumatic infection, the blood-borne streptococci may settle on the valves and set up a subacute bacterial endocarditis. There is a considerable amount of published and unpublished work supporting this association between gum sepsis, tooth extraction, and bacterial endocarditis. More definite proof that the particular strain of *Str. viridans* causing bacterial endocarditis is identical with the organism present in the mouth cannot easily be supplied, since the green-producing streptococci are found to be a heterogeneous group when attempts are made to classify them either by fermentation reactions or serologically. In a paper elsewhere in this issue F. R. Selbie, Rosemary D. Simon, and R. H. M. Robinson describe how serologically similar strains have been isolated from the blood and mouth of patients with subacute bacterial endocarditis, but final proof of identity would require more precise antigenic analysis. In this connexion it may be noted that a particular serological type of non-haemolytic streptococcus called *Str. mutans*, and associated by Kilian Clarke with dental caries, is sometimes the causal organism in bacterial endocarditis. *Haemophilus para-influenzae*, another normal inhabitant of the mouth, is also occasionally associated with bacterial endocarditis. Thus, even if there is no absolute proof that the causal organism is most often derived from the mouth, the evidence is strong enough to justify the use of a "chemoprophylactic umbrella" when any mouth operations are carried out on a patient with damaged heart valves. The questioner should also refer to the leading article at p. 692 of this issue.

Coeliac Disease

Q.—*What are the latest views on the treatment of coeliac disease in children? Is it true that the use of vitamin B and liver therapy has largely removed the need for dietary restrictions? If not, is it important to restrict the intake of carbohydrates as well as of fats? How can an adequate diet, say for a child aged 3, be arranged with present food restrictions? What is the best method of administering the necessary vitamins, and are these obtainable in solution in palatable fat-free form?*

A.—No great advance in the treatment of coeliac disease has been made recently. Three principal forms of diet have been evolved—the low-fat diet, the starch-free normal-fat diet, and the Bircher-Benner diet; in the latter fats are restricted and starchy foods replaced by fruits and salads. In any diet it is wise to restrict starchy foods and essential that there is a high protein and calorie intake. Treatment with injections of liver extract and vitamin B has proved useful, particularly during the acute phases of the disease, but only in addition to dietary measures. It is likely that liver extracts supply some factor which is liable to become deficient in coeliac disease.

It is difficult to devise a suitable diet which is economical and which the child will eat, but the low-fat diet is perhaps the easiest. On receipt of a detailed medical report, including the results of stool analysis, the Ministry of Food allows a child of 3 years five extra rations (the allowance for a child under 5 being half the adult ration) of meat and a tin of half-cream dried milk weekly on the surrender of all fat coupons. Dried bananas are obtainable through food offices, but these are not so popular as the fresh fruit, which are well tolerated when really ripe and which will generally be reserved by a greengrocer when he knows of the child's illness. In the same way a butcher can usually be persuaded to reserve such things as liver. Salads and many fruits are well tolerated. Soya biscuits, or one of the specially prepared breads with a high-protein, low-starch content, can be eaten instead of ordinary bread. Dextrimaltose or glucose can be obtained on a doctor's certificate, and 1 to 2 oz. (28 to 56 g.) should be given daily. Cow's milk should be hand skimmed and given to drink or used to make junkets and puddings. Vitamin C may be given by mouth in the form of concentrated orange-juice, and vitamins A and D as halibut-liver oil or one of the proprietary concentrates in doses of 10 to 20 drops daily. Watery preparations of vitamin A and D are available, but are more expensive and are not essential.

The questioner should refer to *Arch. Dis. Childh.* 1949, 24, 81, and *Practitioner*, 1948, 160, 291.

Dichloracetylene Poisoning

Q.—*What are the toxic effects of dichloracetylene? Have any cases of poisoning been reported, and are there any reports in the literature on the post-mortem examination of fatal cases? If so, what were the essential findings?*

A.—Dichloracetylene is very toxic and unstable, but has little or no use in industry, as distinct from acetylene dichloride (or dichlorethylene), which is less toxic and is an industrial solvent. Dichloracetylene is a liquid boiling at 32° to 33° C. at a pressure of 748 mm. Hg; it is unstable and readily catches fire in air on warming. It is narcotic and causes death from respiratory paralysis. There is a reference in the literature to the corresponding dibromacetylene as an intensely poisonous liquid, causing headaches, indigestion, exhaustion, and most noticeably loss of memory (Lawrie, *J. Amer. chem. Soc.*, 1906, 36, 490), but no reference to any post-mortem findings has been traced. Stringent safety precautions against fire and toxic hazards would be required in the preparation and use of dichloracetylene, and should take the form of complete enclosure in a closed system.

Control of Ants

Q.—*I should be grateful if you could tell me what are the dangers of food being infested by ants and what modern methods are available to protect food from these pests.*

A.—Food is not exactly "infested" by ants in the sense that certain other insect pests live and breed in it. However, the workers of certain species of ant make raids on food in larders, etc., and carry back portions to the nest. Two kinds of house-haunting ants are common in Britain: (*a*) The black garden ant (*Acanthomyops niger*) often enters dwelling-houses through a window or through crevices in the floor. The best control measure is to trace the ants back to their nest in the soil and destroy it. (*b*) In steam-heated institutions, such as hospitals, the tiny sand-coloured Pharaoh's ant (*Monomorium pharaonis*) is a very intractable pest. The nests are deep in the walls and usually inaccessible. Spraying with D.D.T. has been tried without success. The most promising control measure is the use of a poison bait (e.g., 51% water, 0.8% sodium fluoride, and 48.2% thick syrup). The bait is kneaded into small pieces of cake or bread and scattered out of the way of children or domestic animals. Baits must be renewed weekly for at least three or four months to obtain eradication.

Succinate-salicylate Therapy

Q.—*M.'M. Szucs claimed recently that succinate-salicylate therapy was of value in arthritis (Ohio St. med. J., 1947, 43, 1035). What is the theory underlying this method, and have the views put forward by Szucs been confirmed or not?*

A.—The claims made by Szucs for the use of succinate-salicylate therapy in arthritis have not been confirmed by subsequent medical experience. Observers in both Canada and

America, where this work originated, have reported that succinate-salicylate has the value of its salicylate content only, and that the addition of the succinate portion, although attractive in theory, is of no practical clinical advantage.

Effects of Testosterone

Q.—*A male patient aged 53 has been receiving injections of 25 mg. of testosterone dipropionate at weekly intervals for some months, after an initial intensive course of three injections a week, for the treatment of debility. He improved to start with, but he is now very apprehensive about any ill effects. Are there any known ill effects, either near or remote, associated with continued dosage with testosterone dipropionate?*

A.—There are no recorded ill effects from therapeutic doses of testosterone as, for example, those given in the above case. Theoretically, testosterone might produce enlargement of the prostate gland, but this is a theoretical rather than a practical consideration. Theoretically it might also produce enlargement of the pituitary gland and an increase in the number of chromophobe cells, possibly with the formation of chromophobe adenoma, as is possible with massive doses of oestrogens, but here again, in the opinion of the writer, these considerations have no practical bearing on clinical testosterone therapy. In younger people testosterone in large doses, while possibly increasing eroticism and potency and the size of the penis, would cause involution of the testes; but in a patient of 53 this fact would not have the same significance as in a person of 23, and in any case the doses used would have to be much greater to produce this result.

Facial Disfigurement

Q.—*Are there available any cosmetics or other preparations which would enable a young girl suffering from adenoma sebaceum of the face, which causes a good deal of disfigurement, to conceal the marks?*

A.—Special make-up preparations are sold by most of the big cosmetic firms and are designed to hide blemishes and disfigurements. Most of them were developed during the war, and it must be admitted that many are inferior in quality and unsatisfactory in use. This appears to be due to the limitations imposed on the importation of the necessary ingredients for this kind of preparation. A special cream is obtainable from a London firm which has the advantage of covering the defects efficiently without cracking or flaking.

Treatment of Chronic Alcoholism

Q.—*I wish to try "antabuse" on a chronic alcoholic whose liver is somewhat enlarged, and I should like to know if this is a contraindication. If not, what dosage do you recommend?*

A.—"Antabuse," or tetraethylthiuramdisulphide, acts by depressing the oxidation of acetaldehyde, which is presumably due to a depression of liver function. Nevertheless, it is clear that if the patient is cured of his alcoholism his liver may then recover; it is therefore right to try to cure him. The dose is 1.0 to 1.5 g. initially and 0.5 g. thereafter daily. The care required in treatment is indicated in the article by A. E. Carver (*Journal*, August 27, p. 466) and in the earlier paper by Martensen-Larsen (*Lancet*, 1948, 2, 1004).

Aplastic Anaemia and Agranulocytosis

Q.—*What drugs have been known to cause aplastic anaemia and agranulocytosis? Have thyroid tablets or Lugol's iodine ever been incriminated?*

A.—Administration of the following agents has been followed by aplastic anaemia: benzol, the arsphenamines, gold salts, sulphonamides, dinitrophenol, trinitrotoluene, mustard gas and nitrogen mustards, bismuth, mercury, colloidal silver, various hair dyes, volatile insecticides, and possibly analgesics such as amidopyrine, acetanilide, and phenacetin. Agranulocytosis has resulted from the administration of the sulphonamides, thiouracil, amidopyrine and its compounds, gold salts, the arsphenamines, dinitrophenol, and possibly from the barbiturates, phenazone, phenacetin, "neostibosan," quinine, cinchophen, bismuth, phenylethylhydantoin, and pamaquin. Radioactive substances may give rise to either of these syndromes. Neither Lugol's solution nor thyroid tablets have been known to cause agranulocytosis or aplastic anaemia. It should be noted that in many instances there is a personal idiosyncrasy to the causative drug, and with most of these agents the syndromes are rare.

Non-spermicidal Lubricants

Q.—*I have heard that some lubricants used to facilitate intercourse may have a deterrent effect on conception. Is this correct, and can you suggest a suitable lubricant which is free from this disadvantage?*

A.—When conception is desired, it is necessary to ensure that penetration is painless and complete. In many cases this can be achieved only if the vagina is fully lubricated. It is important to avoid petroleum jelly, for, besides being a most unsatisfactory lubricant for the vagina, it has a mechanical action deleterious to sperm activity. There are two or three "water-soluble" lubricants obtainable which have practically no spermicidal action.

NOTES AND COMMENTS

Pus Cells in Semen.—Dr. H. A. DAVIDSON (London, S.W.) writes: The answer to the question on pus cells in semen ("Any Questions?" August 13, p. 398) is liable to mislead the questioner and possibly expose his patient to unnecessary psychological and physical hardship. It is by no means evident from the question that the patient's fertility is impaired. Although it is stated that "motile sperms are absent," no mention is made whether any immotile sperms were found. If they were, one would need to know the age of the specimen and the method of collection, for even normally fertile semen, if too old or collected in a condom, might contain no motile spermatozoa. The answer states that an attempt must first be made to discover the source of the pus cells. It would seem more urgent to ascertain first whether in fact the patient is subfertile or not. Normal semen may contain up to two million leucocytes per millilitre, and even frank pus admixed from the prostate, seminal vesicles, or urethra would not necessarily impair its fertilizing capacity. It is disturbing to read the statement, on such incomplete evidence, that the outlook is poor, and, much as one would agree with the need for testicular biopsy if in fact the semen contained few or no spermatozoa, one wonders why the finding of "healthy testicular tissue" should call for an attempt to stimulate spermatogenesis. Finally, an obvious slip of the writer's pen should be rectified: Chorionic gonadotropin is prepared from pregnancy urine and not, as stated, from pregnant mares' serum.

Herpes, Varicella, and Queen Anne.—Dr. W. A. BELLAMY (Aylesbury, Bucks) writes: For some years now the *Journal* has printed numbers of letters from correspondents who have noticed the incidence of herpes and chicken-pox in the same patient. Is it not time we all realized that Queen Anne's dead?

Correction.—Dr. A. G. WATKINS (Cardiff) writes: In the acknowledgments at the end of the article "Incidence of Cross-infection in Children's Wards" (September 17, p. 616), in acknowledging a grant towards computing expenses, it was wrongly stated that the grant was made by the British Paediatric Association. It is the Ministry of Health to whom the authors are indebted, and they take this opportunity of apologizing for this mistake.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology, Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Britmedads, Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra, Westcent, London.*

SUPPLEMENT TO THE
BRITISH MEDICAL JOURNAL
LONDON SATURDAY SEPTEMBER 24 1949

THE SECRETARY REPORTS

GENERAL MEDICAL SERVICES

With the major issue of remuneration awaiting discussion with Ministry officials on September 23, the General Medical Services Committee was able, at its meeting last week, to devote a full day to routine business, most of the points concerning the terms and conditions of service of general practitioners. Here are some of the points dealt with.

(*a*) There has been a good deal of concern during the past year about the extent to which executive councils' lists are inflated—i.e., the extent to which persons appear on the list twice. No doubt clerks of executive councils have done their utmost to eliminate this. Yet from time to time evidence is forthcoming that inflation still exists. Following the committee's representations on the point, the Ministry of Health has arranged by way of an experiment for a few executive councils to send to a number of persons whose identity numbers are not known a communication asking for those numbers. The reply is being prepaid, and if the result of the experiment shows that a measure of inflation has been eliminated general action of a similar kind will be considered.

(*b*) It has been decided to ask the Ministry to add to the list of appliances which general practitioners may order for their patients ligature material, male and female urinals, and "lastonet."

(*c*) The committee's legal advisers take the view that a doctor in the Service is required under the regulations to issue Ministry of National Insurance certificates to a patient even though he may know that the patient is receiving treatment from an unqualified person. This intolerable position arises because the certification regulations for the new Service have not exactly followed those in force under National Health Insurance. The committee is taking up the point with the Ministry.

(*d*) The committee examined the administration of the Special Inducement Fund in the light of experience gained in the first year of the Service. It is not satisfied that the method of dealing with applications conforms with the original discussions on the application of this fund. The committee intends to put to the Ministry a proposal for widening the scope of the fund so as to include definite cases of hardship.

(*e*) The committee has approved a draft circular which the Home Office intends to issue for the guidance of police authorities in connexion with emergencies involving the services of general practitioners. It is felt that this circular will clarify the position.

Temporary Residents

It is clear from the correspondence coming to this office that there is still some confusion about the procedure to be followed by patients seeking treatment as temporary residents. Anyone staying away from home for a period of less than three months can apply to any public practitioner for treatment as a temporary resident. It is not necessary for the applicant to produce a medical card or to be on the list of a public practitioner in the home area. Having accepted and treated a temporary resident, the practitioner claims payment by filling in and returning to the local executive council of his area a form (E.C.19) provided by that body for the purpose. The same arrangement applies to anyone moving from place to place. If the period of stay extends beyond three months the residence is no longer regarded as temporary.

Remuneration of Colonial Medical Officers

The Working Party of officials from the Colonial Office and B.M.A. House which has been assessing the monetary value of all the various advantages and disadvantages of a Colonial medical officer's life has now completed its work and presented its report. The task has been difficult, and the Working Party has had the assistance of an actuary and an accountant and other experts. In due course it is intended to publish a full report of these calculatiohs and of the current negotiations with the Colonial Office. No further statement can be made at present, as the outcome of the negotiations depends to some extent upon the discussions which are now proceeding with the Ministry of Health on the betterment factor which has been or ought to be applied to the Spens recommendations.

Dentists' Hours of Work

One always suspected that much of the criticism which the dental profession has been receiving in recent months was both ill-informed and unfair. The Report of the Ministry of Health Working Party on Chairside Times, which is summarized on another page, confirms these suspicions. "Most dentists," says the Report, "are working longer hours than is comfortable, or than would be good for them if continued for too long a period, and many of them are working more quickly than they would normally. These conditions have been forced upon them by the influx of work which has resulted from the expanded Health Service. As a body they have been trying to cope with the difficult problem of keeping pace with demand without loss of efficiency, and, as a body, the Working Party thinks that they should have received more gratitude and less adverse criticism than has actually been the case." The Report states that the "comparatively few cases of very long hours (and of very high earnings) should not be regarded as a major factor when terms of service are under consideration. Such cases should be judged from the point of view of efficiency only." "Up to the point where efficiency becomes impaired, neither the State nor the patient suffers from the excessive efforts" of "a comparatively small minority." "It has to be recognized," adds the Report, "that by means of organization and careful management output (or should it be 'input'?) can be increased to a considerable extent without loss of efficiency."

Arbitration Award

I was particularly interested to read that the salaries of secretaries of boards of governors, sometimes known as house governors, have been dealt with by an Industrial Court. The award should prove of interest to those engaged in medical administration. It is as follows:

Salary on appointment	£1,750 per annum
After one year's service	£1,800 „ „
After two years' service	£1,850 „ „
After three years' service	£1,925 „ „
After four years' service	£2,000 „ „

(plus a weighting allowance of £50 per annum in the Metropolitan Police Area).

Officers already in posts in July, 1948, in hospitals which were then transferred into the National Health Service are to have the option of remaining on the salaries or salary scales and other conditions of service which they had before July, 1948, if these were more favourable than those of the award.

TERMS AND CONDITIONS OF SERVICE OF HOSPITAL STAFFS

The Ministry of Health has amended the Terms and Conditions of Service of Hospital Medical and Dental Staff for England and Wales (*Supplement*, June 11, p. 314). Details are given below.

Remuneration and Grading

Main Scale for Consultants (Document, paragraph 1 (*a*)).—A practitioner appointed as a consultant before the age of 30 should start at a salary of £1,400 per annum, rising to £1,550 per annum after one year's service, to £1,700 per annum after two years' service, and thereafter in accordance with the scale set out in paragraph 1 (*a*) (1) of the document. He should *not* remain on a salary of £1,400 per annum until he reaches the age of 31. In effect, the salary scale for consultants is a continuous scale from a minimum of £1,400 per annum to a maximum of £2,750 per annum; and under paragraph 1 (*a*) (2) of the document age merely determines the point of entry to this scale.

Senior Hospital Medical and Dental Officers (Document, paragraphs 2 (*a*) and (*b*)).—There is no provision in the Terms of Service for the remuneration of senior hospital medical officers or senior hospital dental officers below the age of 32, and it is not intended that any officer below the age of 32 should hold such an appointment. Any officers below that age who have not been graded as consultants should therefore be graded as senior registrars, junior hospital medical officers, or general practitioners under paragraph 10 (*b*) or 11 of the document, as appropriate.

Medical Superintendents and Deputy Medical Superintendents (Document, paragraph 2 (*c*); see also paragraph 15).—The reference to the particular grades of consultant or senior hospital medical officer cannot override the grading of a particular officer by a professional review committee. If a medical superintendent or deputy has been graded in some other grade, the whole-time salary of that grade will be used for the purpose of the calculation under (i). The word "etc." should be inserted after "senior hospital medical officer."

Part-time Appointments

Appointments with More than One Board (Document, paragraph 5 and R.H.B. (49) 100/B.G. (49) 84).—R.H.B. (49) 100/B.G. (49) 84 refers only to consultants, but the principles laid down in that memorandum should be applied also to medical and dental officers of any grade who hold appointments with more than one board or management committee.

Residence.—A residence clause has been included in the *pro forma* contract for whole-time consultants and senior hospital medical and dental officers, and it has been assumed that residence may be required as a matter of course in the case of house officers, other resident junior officers, certain medical superintendents, etc. Guidance has been requested on residence conditions for part-time consultants and other part-time senior officers living considerable distances from the hospitals where their principal duties lie and having no private consulting-room nearer the hospital (see paragraph 19 (*b*) of the document). This may involve, in some cases at least, the payment of wholly unreasonable sums, not only by way of travelling expenses but also in taking travelling time into account in arriving at the number of notional half-days from which remuneration is calculated. If the officer's duties do not make it essential for him to reside within a certain distance of the hospital where his principal duties lie, and he himself wishes to live further away, a residence condition need not be insisted upon; but where the officer who has no nearer private consulting-room lives more than 10 miles or a half-hour's journey away from the main hospital, boards should, unless the circumstances of the individual warrant exceptional treatment, and as an alternative to requiring residence within a certain distance of it, apply a maximum of 10 miles (each way) to the appropriate allowance for travelling expenses in getting to it, and half an hour (each way) to the travelling time taken into account in assessing the number of notional half-days under paragraph 5 (*a*) of the document.

Work Done for Colleagues during Holidays, etc. (Document, paragraph 5).—Anticipated duties under Clause 7 of the *pro forma* contract for part-time officers (i.e., time which it is known will be given in doing colleagues' work during holidays) should be taken into account in the pre-contract assessment of the average number of hours per week on which the part-time remuneration is based, and not paid at locum rates. This does not, of course, affect the application of the maximum under paragraph 5 (*d*) of the document. It is open to boards to vary the wording used in Clause 7 of the *pro forma* contract so as to include duties at other hospitals than those mentioned earlier in the contract.

Locumtenent Arrangements (Document, paragraph 7)

(*a*) *Locums Standing in for Whole-time Officers.*—The rates of payment in paragraph 7 of the document are related to notional half-days. The table in paragraph 5 (*a*) of the document should therefore be used in determining the number of half-days. Locums whose duties amount to more than 28 hours per week (including those who are replacing whole-time officers) would thus be paid for nine half-days per week—i.e., in the case of consultants, 45 guineas per week; in the case of senior hospital medical officers, 31½ guineas per week.

(*b*) *Application of the Lower Rate.*—Any practitioner other than a consultant who is doing duty as a locum in a consultant post should be paid at the 3½-guinea rate. Any practitioner doing duty as a locum in a post other than consultant, registrar, junior hospital medical officer, or house officer should be paid at the 3½-guinea rate.

(*c*) *House Officers, Junior Hospital Medical Officers, and Registrars.*—As stated in paragraph 31 of R.H.B. (49) 85, engagement of a locum should in practice rarely be necessary in the case of absence of any officers other than those specially referred to in paragraph 7 of the document. Where, in very exceptional circumstances (e.g., during sickness when no arrangements can be made), engagement of a locumtenent to fill a house officer, junior hospital medical officer, or registrar post cannot be avoided, the locum should be paid for the period of his services at the same rate as the officer whose place he is filling. No higher rate should be paid without the prior approval of the Minister.

Part-time Consultants Performing Teaching Duties (Document, paragraph 9 (2))

Paragraph 9 (2) of the document should be amended by deleting the words "or separately from" and "like other consultants" and inserting the words "for this clinical work" after "remunerated." This expresses without ambiguity the original intention. Remuneration for teaching duties which are separate from clinical work (e.g., lectures, tutorials, etc.) is the responsibility not of the board but of the university or medical school. Such duties (as distinct from teaching during ward rounds, out-patient clinics, etc.) are not considered to be "clinical work" under this paragraph and should therefore not be taken into account in the pre-contract assessment, under paragraph 5 (*a*) of the document, of the time required for the duties attaching to the post.

Transferred Officers (Document, paragraph 12 (c))

(*a*) *Transferred Officers who Choose to Accept the New Terms and Conditions of Service.*—Officers whose salary before transfer (including any value attached to emoluments) was higher than the salary which they would receive, under the new terms and conditions of service, from July 5, 1948, and who choose to accept the new terms and conditions of service, shall enter the new salary scale at their existing salary (determined as below) but shall remain on that salary on a mark-time basis until the new scale overtakes it. In cases where emoluments were previously enjoyed, the mark-time salary shall be an inclusive figure arrived at by adding the value of the

emoluments to the old cash salary. The mark-time salary so determined shall be subject to the appropriate deduction under paragraph 17 of the document.

(*b*) *Distinction Awards.*—The monetary value attaching to a distinction award is an element in remuneration (as stated in paragraph 1 (*b*) of the document). A consultant who has exercised the option under paragraph 12 (*e*) is therefore not entitled to receive any payment in respect of a distinction award subsequently made to him so long as he remains on his previous salary scale and conditions of service. Under paragraph 12 (*e*) as now drafted he would be obliged to do so as long as he remains "in the same appointment or another appointment of the same or greater responsibility," carrying a basic salary scale below that which he enjoyed before July 5, 1948. Such an officer should, however, be allowed to reconsider his option if he receives a distinction award. In order to introduce this change without further complexity of language, paragraph 12 (*e*) of the document has been redrafted: the following revised version should be substituted:

(*e*) *Transferred Officers.*—Officers who were transferred under *Section 68 of the National Health Service Act, 1946, shall be entitled* to retain their previous salary scale and conditions of service (including emoluments) on a personal basis for as long as they remain in the same appointment, provided that travelling and subsistence allowances as set out in paragraph 19 shall be adopted for all officers irrespective of the allowances for which they may have been eligible before transfer.

On taking up a new appointment or on promotion, however, they shall conform to the new rates of remuneration and conditions of service: provided that if in comparison with the post held at the appointed day the new appointment is of equal or greater responsibility, measured by the rate of remuneration, they may choose to continue on their pre appointed-day remuneration and conditions of service (except for travelling and subsistence allowances): for the purposes of this proviso the conferment of a distinction award shall be treated as a new appointment.

Incremental Dates

In the case of officers holding appointments at July 4, 1948, who do not elect to retain their previous salary scale and conditions of service, the salary payable from July 5, 1948, is determined in accordance with paragraph 12 of the document, and whatever the date of first appointment the next increment on the new scale would be payable on July 5, 1949. For example, a practitioner appointed as a consultant on August 1, 1945 at the age of 32 would be paid a salary of £1,950 per annum from July 5, 1948, and would receive his next increment on July 5, 1949.

Retention of Fees (Document, paragraph 14)

In former public assistance institutions which now provide both hospital accommodation under Part II of the National Health Service Act and residential accommodation under Part III of the National Assistance Act, there is no objection to a member of the medical staff of the hospital having a limited "list" to enable him to give services under Part IV of the National Health Service Act to any residents in the "Part III accommodation" who choose him as their family doctor. In this case the same limitations should apply as to the limited lists referred to in paragraph 58 of R.H.B. (49) 85/H.M.C. (49) 70/B.G. (49) 71. Any capitation fees received would be kept by the practitioner concerned, the work being regarded as within Category II of paragraph 14 of the document. Accordingly, in paragraph 14 (1) of the document the words "(except in respect of members of the hospital staff)" should be amended to read "(except in respect of patients for whom he is allowed a limited 'list'—e.g., members of the hospital medical staff)."

Tenure of Post (Document, paragraph 15)

By virtue of paragraphs 15 and 16 of the document, a consultant who is over 70 is not permitted any kind of paid appointment (although, as indicated in paragraph 65 of R.H.B. (49) 85, domiciliary consultation fees may be paid to him). It is recognized that there may be cases where a consultant over 70 can quite properly and usefully be employed on duties which are limited in scope—e.g., as consultant adviser to a regional board, visiting outlying hospitals for "pastoral visits," etc.—and there is no reason why such an arrangement should not be made and paid for in the usual way. In no circumstances, however, should a consultant over 70 be employed in a paid capacity in such a way as to block promotion for younger officers. It would, for example, be wrong for the duties attaching to a post to be reduced at any time because certain of them were given to a consultant over 70.

Subsistence Allowances (Document, paragraph 19 (f) (3))

The following proviso, *omitted in error in revising earlier* versions of the proposed terms of service, should be inserted before proviso (*a*) in paragraph 19 (*f*) (3) of the document:

"(*a*) day allowance shall not be paid in respect of any period spent at a hospital as part of the normal duties of the officer concerned;"

The present provisos (*a*) and (*b*) should become (*b*) and (*c*).

Membership of Medical Defence Societies

It is understood that some hospital authorities have in the past required members of their medical staffs to be members of a medical defence society. The Minister sees no objection to the continuance of this practice.

Medical Superintendents of Mental Institutions (Document, paragraph 2 (c))

Questions have been raised regarding the interpretation of paragraph 2 (*c*), which refers to the computation of the salaries of medical superintendents in relation to clinical and administrative duties, particularly in the case of medical superintendents of mental hospitals and mental deficiency institutions.

R.H.B. (49) 85/H.M.C. (49) 70/B.G. (49) 71 stated (paragraph 11) that in computing the salary rates of these officers "boards may ignore any administrative duties of which they find it impracticable to relieve a medical superintendent where these duties occupy only a small proportion of the officer's time." Regional hospital boards will, of course, bear in mind the importance of reducing to a minimum the time given by the medical staff to administrative work. But they should take into account the fact that the position of medical superintendents in mental hospitals and mental deficiency institutions is affected by the requirements of Statutory Instrument, 1948, No. 419, under which the medical superintendent's special position as chief officer necessitates his exercising a general control over all departments of the mental hospital or mental deficiency institution. Moreover, much of the work which is sometimes regarded as administrative necessarily falls to the medical superintendent because it is essentially clinical in character. Under this heading would come the statutory medical work and the activities directly connected with the treatment, training, and occupation of patients, as well as general supervision of entertainments and the provision of amenities. As the medical superintendent is the person to whom any order of detention is addressed, the arrangements for the general welfare of patients are his concern both as a clinician and as an administrator. But the time given to purely administrative work need not, it is estimated, exceed 10% of the time given by a whole-time officer, and this may properly be regarded as so small a proportion of the time that there need be no abatement of the remuneration at clinical rates for the whole of his time.

BLIND PHYSIOTHERAPISTS AND THE N.H.S.

Sir Ian Fraser, M.P., chairman of St. Dunstan's, speaking at the annual conference of St. Dunstan's physiotherapists at Brighton on September 10, stated that he had led a deputation of physiotherapists to see Mr. Bevan. They had asked that private practices among blinded physiotherapists should be encouraged, or at any rate should not be discouraged. It was now clear, said Sir Ian, that discouragement was to be their portion; they must more and more fend for themselves. Mr. Bevan, however, had issued a circular to hospital regional boards urging them to favour the employment of blind physiotherapists in the National Health Service (*Supplement*,

September 17, p. 136). While most of them preferred private practice, they thanked the Minister for this. Sir Ian added that in his judgment the N.H.S. might diminish private practices but it would not destroy them altogether. So long as there was freedom of choice left to the individual there would be some people who would prefer treatment by a doctor or physiotherapist outside the Health Service.

Dr. Charles Hill expressed his sympathetic understanding of the desire of the blinded physiotherapist for private practice and advised them to follow every move in the National Health Service and work out their particular proposals on a short-term policy. The danger of the N.H.S., he said, was the danger usually associated with big machines or concerns—namely, a centralized control and the loss of freedom of action or choice by the individual.

The conference was attended by about 100 ex-Service blinded physiotherapists, all members of the Chartered Society of Physiotherapy. The assembly included physiotherapists from all parts of England, Scotland, Wales, and Ireland, some of whom were blinded in the first world war and some in the second, and also a sprinkling of men of the last war who are still in their studentship but who took the opportunity of meeting future colleagues and of becoming acquainted with existing conditions in the blind-physiotherapy world.

HOSPITAL ESTIMATES

The Ministry of Health has sent a circular to hospitals describing the basis on which their estimates should be prepared.

Maintenance Expenditure

The Minister asks that the strictest economy should be exercised and that provision should be made only for new services and the extension of existing services to such extent as the board considers to be urgently necessary and practicable. In preparing the estimates the provisions of the Nurses Bill now before Parliament should be disregarded. When the Bill becomes an Act guidance will be given on the financial provisions as they affect hospital maintenance expenditure, and any adjustment necessary can then be made when the revised estimates for 1950–1 are prepared in the autumn of 1950.

Capital Expenditure

The Minister is aware that many urgent schemes are under consideration and is investigating whether it will be possible, within the financial and productive resources that can be made available to the social services, to make available in the next few financial years a larger share for hospital works. If an adequate place is to be secured in the allocation of national resources for urgently necessary hospital developments, it is essential that the Minister should have before him outline programmes of essential works for three years ahead.

For the year 1950–1 boards should draw up their urgent capital works programme as a part of an ordered programme extending over the financial years 1950–1, 1951–2, and 1952–3. The starting point for the programme for 1950–1 will be the expenditure on works initiated in 1949–50 to which the boards are already committed. In order that schemes of war damage repair may be allowed for, these should be indicated specially.

The outline programmes for 1951–2 and 1952–3 should indicate as nearly as practicable the principal development works likely to cost more than £10,000 together with a rough estimate of the magnitude of the expenditure involved. A provisional figure for works under £10,000 should be included, but the works need not be specified. Boards will not be held strictly to the outline programme when the time comes for drawing up their capital estimates for 1951–2 and 1952–3, since each outline programme must be open to review when the actual estimate for any year is being prepared, but an early indication of their content will enable them to be discussed informally in good time with the Ministry, thus reducing the need to examine them when the time comes for formal submission. Boards should draw up their scheme in such a way that if reduction proves necessary when the estimates for 1950–1 are considered a portion of the work planned can be moved forward into the following year.

Capital Estimates for 1950–1.—Regional hospital boards should submit a list of capital works in the regulation form in three parts:

(1) Works in progress at March 31, 1950, with the expenditure falling in the year 1950–1.

(2) Proposed works to be started in 1950–1, with the expenditure falling in that year and that required in later years to complete them.

(3) Reserve list of essential works which should be started in 1950–1 if possible, similarly divided as to expenditure for 1950–1 and later years; the presumption would be that if any of these works have to be deferred they will have the first call on the budget for 1951–2.

The total for (1) plus (2) should not exceed the figure of total capital expenditure notified in March, 1949, for the year 1949–50. The total for (3) should be approximately 50% of the total of (1) and (2). Boards of governors should submit similar lists. The lists should be restricted to really urgent projects, and in the case of London undergraduate hospitals *and the provincial teaching hospitals the total for (1) plus (2)* should if possible be kept within the range £50,000 to £100,000 according to need; in the case of the London postgraduate hospitals within a range of £10,000 to £60,000 according to size of hospital and need; the total for (3) should normally not exceed one-third of the total for (1) and (2).

Outline Programmes for 1951–2 and 1952–3.—In the case of regional hospital boards the total for 1951–2, including the amounts to be carried forward if *all* projects in lists (1), (2), and (3) for 1950–1 are put in hand as planned, should not exceed twice the total of (1) and (2); similarly, that for 1952–3 should not exceed three times that amount.

As regards boards of governors, the rate of capital expenditure on teaching hospitals during the past year or so has been proportionately much higher than at other hospitals. The outline programmes for 1951–2 and 1952–3 should therefore be kept within the same limits as those given for the capital estimates for 1950–1. The same reservation about increases to meet special needs of individual hospitals applies, however.

Exceptional provision will, if possible, be made for starting one new major hospital project in 1951 and another in 1952.

These figures represent the maximum which the Minister can hope to be allocated for hospital development in the years in question. The actual amounts will depend on economic considerations and the needs of other social and industrial services, and may well be substantially less.

GROUP PRACTICE

The Department of Health for Scotland has sent executive councils a memorandum on ways in which general practitioners "may find it helpful to work in co-operation." Recommendations were prepared by a special subcommittee of the Scottish Health Services Council, and they have been endorsed by the Standing Advisory Committee on General Practitioner Services.

The following developments appear to the committee to be desirable and feasible:

(1) Many general practitioners already give mutual assistance in greater or less degree by deputizing for each other in absence. In the committee's opinion many such agreements could with advantage be expanded to enable a group of practitioners to give mutual relief in off-duty periods.

(2) In the same way, arrangements might be made among a group of general practitioners for the receipt of telephone messages for any of their number who are not immediately available—such arrangements to make provision for the calling of a deputizing doctor in urgent cases.

(3) A group of neighbouring doctors might combine in the employment of clerical assistance.

(4) There might be provided simple laboratory and other aids to diagnosis for the benefit of a group where it would not be feasible to make such provision for an individual practitioner.

(5) Co-operation between a group of general practitioners on the one hand, and district nurses and health visitors on the other, might be furthered by arrangements made between the group and the local authority.

(6) Similarly, arrangements might suitably be made between groups of general practitioners and particular hospital units for consultation references, clinical discussions, and ward visits.

The committee recommends that, as a first step, the Secretary of State should ask each executive council and the local authorities in its area to review conditions there, and to consult together on arrangements which might usefully be made to implement all or any of these suggestions. The executive councils, before entering into discussion with the local authorities, should consult the respective local medical committees, who have already been approached in this matter by the British Medical Association. At the stage they consider appropriate executive councils should indicate to the appropriate boards of management of hospitals what part the hospital service might play in making these arrangements and invite their help.

OVERWORKED DENTISTS

REPORT OF WORKING PARTY

The majority of dentists who took part in the survey carried out by the Working Party, whose report has recently been published,[1] "are working at a pace which is punishing, and which many of them realize cannot be maintained."

The Working Party was appointed by the Minister of Health and the Secretary of State for Scotland in February of this year "to ascertain the average chairside time taken by general dental practitioners in England, Wales, and Scotland (1) in the National Health Service and (2) in private practice to complete each of the types of dental treatment set out in Part I of the First Schedule to the National Health Service (General Dental Services) Fees Regulations, 1948, excluding any items for which it is impracticable to establish an average time—e.g., orthodontic treatment." Its members were: Mr. W. Penman, F.I.A. (chairman), Mr. J. J. Gillard Bishop, L.D.S., Mr. A. H. Condry, Mr. J. Lauer, L.D.S., Mr. A. Macgregor, L.D.S., with, as secretaries, Mr. S. Donald Cox and Mr. L. G. Hitching, L.D.S.

The number of letters sent out for the main inquiry was 505, and 261 returns were received. Information was also obtained from 52 dentists working in dental practices of a "clinic" type, and from 16 dentists not engaged in the General Dental Services.

As a result of its inquiry the Working Party considers that most dentists are working longer hours than is comfortable or than would be good for them if continued for too long a period, and many of them are working more quickly than they would normally. These conditions have been forced upon them by the influx of work which has resulted from the expanded Health Service. They have been trying to cope with the difficult problem of keeping pace with demand without loss of efficiency, and the Working Party considers that they should have received more gratitude and less adverse criticism than has actually been the case. There is little hope of an early improvement. The present volume of work is limited by the inability of dentists to do any more, and it will probably be many years before there is any appreciable increase in the number of dentists.

Chairside Hours

The Spens Committee considered that, in general, working more than 33 hours a week at the chairside tends to impair efficiency, and that 33 chairside hours a week means about 42 working hours a week. The Working Party found that 70 dentists were working for a shorter time than the Spens standard, 25 were working to about the standard, and 166 were working for longer. On the average these 166 dentists did 73% of the work, their work on the average being 25% in excess of the Spens standard. Commenting on the Spens Committee's observation that work beyond the standard hours tends to impair efficiency, the Working Party remarks that the dentists' replies disclosed an abnormally high percentage of sickness.

The Working Party recognizes that certain dentists are working too long, too quickly, and with an eye fixed too closely on the monetary reward for their labours, some of them to such an extent as to create grave doubts about whether they can be working efficiently. But by means of organization and careful management work can be increased to a considerable extent without loss of efficiency. The comparatively few cases of very long hours and very high earnings should not be regarded as a major factor when terms of service are under consideration: they should be judged from the point of view of efficiency only.

Private Practice

Comparing the work of private dental practitioners not in the Health Service with that of Service practitioners, the Working Party found that private practitioners did a larger proportion of fillings and a much smaller proportion of extractions and dentures. The private operations of dentists in the National Health Service when compared with their Service operations show a reduction in the proportion of fillings and a very large increase in the proportion of extractions. The Working Party suggests "with some diffidence" that to a large extent this private work is done for people who are in a hurry.

The private work done by Service dentists represents only about 41% of their total operations. The Working Party regards that figure as disposing of the suggestion which has sometimes been made that any considerable section of the dental profession is using the National Health Service on a substantial scale as a cloak under which to obtain comparatively high private fees as the price of giving priority treatment.

Earnings

On the average the National Health Service dentists were earning about 19% in excess of the Spens standard prior to the introduction of the now abandoned "ceiling" of £409 a month (plus half the fees in excess of this sum) and the subsequent reductions in many items of the scale of fees. The remuneration for N.H.S. work was about 14% in excess of the Spens standard, and the other 5% is an estimate of the amount attributable to private work. This 19% is covered as to about 11% by hours in excess of the Spens standard, and as to about 8% by speed of work in excess of what was assumed in 1948. Although the times taken for private work are usually somewhat longer than the corresponding times for National Health Service work, they are not unduly longer.

LOAN OF PATIENTS' RECORDS

The Ministry of Health has informed hospitals that patients' records may be lent on request to the medical boards and medical appeal tribunals of the Ministry of National Insurance to help the assessment of claims for disablement benefit, provided that the Ministry of National Insurance first obtains the consent of the patient in writing. The papers will be treated as confidential, and will be handled only by the regional medical officers (and their confidential lay staff), boarding doctors, specialists to whom claimants may be referred, and, in the case of appeals, by the members of the appeal tribunal.

Photostatic copies will not be made, but the regional medical officer may make extracts of the relevant portions of the case papers which have been taken into account by the medical boards. The patient will not be given information other than those extracts which are directly relevant to his claim, and if these extracts contain any information which might be harmful to the claimant the regional medical officer will take care to give it only to the claimant's own doctor or, as appropriate, to his trade union or legal representative.

GENERAL MEDICAL SERVICES COMMITTEE

A meeting of the General Medical Services Committee was held on September 15, with Dr. S. Wand in the chair. The chairman welcomed Mr. J. G. Gilbert, who was present for the first time as a representative of the British Dental Association.

The chairman reported that owing to the absence of senior officials of the Ministry of Health on holiday it had not been possible to arrange a meeting on the question of remuneration before September 23.

Absenteeism and Medical Certification

The chairman said that there had been comments in the Press following the Prime Minister's statement to the Trades Union Congress on absenteeism, and some of these comments reflected on the integrity of practitioners in giving certificates.

In the course of discussion it was strongly denied that laxity in certification was a major factor. Several other likely factors were mentioned in the experience of those concerned. In general, people were taking more notice of minor ailments, there was a disposition to stay longer on the sick list, as the original Beveridge report had foreseen, and another factor was the reluctance of patients to re-start work in the middle of the week.

A letter was read from the Ministry of Health laying it down that fees for medical examinations of candidates for appointments in the National Health Service should be paid by the appointing authority. It was mentioned—not in the letter—that the maximum fee which hospital authorities were permitted to pay was one guinea. The committee took the view that as it had been agreed that for similar examinations on a short form for candidates for appointments in Government departments a fee of 25s. should be paid, which fee had been obtained in many instances, this should be the recognized fee for medical examination of National Health Service staff.

Rural Mileage

Dr. J. C. Pearce, chairman of the Rural Practitioners Subcommittee, presented a report the principal matter in which concerned mileage. He said that various criticisms of the mileage arrangements had been made, and the first thing that the subcommittee had set itself to do was to make sure that the global sum was sufficient. For that purpose an inquiry had been made. While the population for whom mileage was paid had gone up two and a half times, the mileage grant had gone up three and a half times. The subcommittee felt that the global sum must be regarded as sufficient. The trouble really arose over distribution, in which there were obvious anomalies. The subcommittee's view was that it would be best to leave the question of local distribution to determination by the area concerned, and to ask local medical committees to supply detailed information of practices containing peculiar difficulties or hazards (e.g., mountainous areas, islands, lighthouses, etc.), which should be dealt with in a special way.

The chairman said that it had now been proved that the pool was reasonably adequate, but that the distribution in the past had been not quite fair. It was known that there were some desperately bad cases which would have to be looked into with a view to making special arrangements; but in the ordinary way of straightforward mileage he hoped that rural practitioners would agree that on the new basis of redistribution of an adequate pool they could try it out for at least twelve months.

Insurance Certificates and "Covering"

An interesting point was brought forward on a question of "covering" an unqualified practitioner. The solicitors to whom the point had been referred held the view that a practitioner had an obligation under existing regulations to issue insurance certificates even though he knew that the patient was receiving treatment from an unqualified practitioner. It appeared that whereas in the old Medical Certification Rules it was stated that medical practitioners "who are attending" insured persons should give certificates, the N.H.S. Regulations, 1948, omit the quoted words. There are also other differences between the two sets of regulations.

One member suggested that a practitioner who gave a certificate to a patient whom he knew to be attended by an unqualified practitioner would be transgressing the Warning Notice of the General Medical Council, though it was difficult to visualize the General Medical Council taking action against a practitioner who was only fulfilling his contract.

Domiciliary Midwifery

The chairman made a brief report on the document on the domiciliary midwifery service approved by the Central Health Services Council which was sharply condemned by the committee at its last ordinary meeting. Unfortunately, the document was issued before the committee had any opportunity of formulating its objections. The Ministry had received a deputation from the committee, and it was thought that much good would come from the interview. The matter was the subject of an annotation in the *Journal* of August 6.

The committee received with much appreciation, and noted for future use, a report by the Middlesex Local Medical Committee on a questionary issued to general practitioners in Middlesex on the maternity medical list. It gave the replies of 293 practitioners, with figures, concerning confinements they had attended, the liaison with the midwife, the use of analgesia or anaesthesia, and certain questions connected with rate of payment.

Association Notices

TITLE OF BIRMINGHAM BRANCH

Notice is hereby given by the Council of the Association to all concerned that it is proposed to alter the title of the Birmingham Branch to the "Midland Branch."

Any member or body affected by this proposal and objecting thereto is requested to write to the Secretary of the Association by October 24, 1949, stating the objection and the ground therefor.

CHARLES HILL,
Secretary.

Diary of Central Meetings

SEPTEMBER

27	Tues.	Organization Committee, 11.30 a.m.
28	Wed.	Private Practices Committee, 2 p.m.
29	Thurs.	Non-professorial Group Committee, 2 p.m.
29	Thurs.	Ethical Rules Subcommittee, 2 p.m.
29	Thurs.	International Relations Committee, 2.30 p.m.
30	Fri.	Ophthalmic Group Committee, 2 p.m.

OCTOBER

4	Tues.	Committee on Relationship of Autonomous Bodies, 2 p.m.
5	Wed.	Joint Committee of British Medical Association and National Veterinary Medical Association, 2.30 p.m.
14	Fri.	Committee on Industrial Health Services in relation to the National Health Service, 2 p.m.
18	Tues.	Proprietary Medicines Committee, 11 a.m.

Branch and Division Meetings to be Held

MID-ESSEX DIVISION.—At Chelmsford and Essex Hospital, Sunday, October 2, 10 a.m. Dr. H. Bathurst Norman: "The Cardiac Bruit."

NORFOLK BRANCH.—At Nurses' Lecture Room, Norfolk and Norwich Hospital, Thursday, September 29, 3.30 p.m., annual meeting. Address by Dr. W. A. R. Thomson: "Compound E in the Treatment of Rheumatoid Arthritis and Rheumatic Fever."

SOUTH ESSEX DIVISION.—In Nurses' Lecture Theatre, Oldchurch Hospital, Romford, Tuesday, September 27, 9 p.m., lecture by Dr. W. Evans: "Pitfalls in Cardiological Diagnosis."

WEST MIDDLESEX DIVISION.—In Princes Room, Ealing Town Hall, 8.30 p.m., "The Modern Outlook on Food-poisoning," Professor Robert Cruickshank.

FAT ABSORPTION AND SOME OF ITS PROBLEMS*

BY

H. S. RAPER, C.B.E., D.Sc., F.R.C.P., F.R.S.

Dean of the Medical School and Professor of Chemical Physiology, University of Manchester

Some twenty years ago physiologists considered that the process of fat absorption was largely understood. Fats were supposed to be taken up by the intestinal cells only after hydrolysis to fatty acid and glycerol, and neutral fats were never absorbed as such. Furthermore, since free fatty acid, although well absorbed, is not found free in the chyle, it was assumed that reconversion of fatty acid and glycerol to neutral fat occurred in the cells of the villi, and that this neutral fat was then passed on into the lacteals. There was no suggestion then that any portion of the fatty acids which were produced by hydrolysis of the food fat escaped this process of resynthesis and gained access as such to the blood or the lymph. But there was not then, and there is not now, sufficient quantitative evidence to tell us exactly what happens to the whole of the fat absorbed after any one meal.

This picture of the mechanism of fat absorption, accepted as largely true, as I say, twenty years ago, has had considerable doubt thrown upon it in the last decade. But it was not as complete as I have suggested even before then, for the passage of fat from the cells of the villi to their central lacteals was not understood. Sharpey-Schafer had suggested from histological investigation that this transfer was carried out by amoeboid cells in the reticulum of the villus. But the difficulty of accounting for the speed at which fat absorption may take place by the unaided activity of these cells has not supported Sharpey-Schafer's view. What is more probable is the view of Verzar that the pumping action of the villi causes fat to enter the central lacteals, and that the absorption not only of fats but of other substances is promoted in this way.

Earlier Beliefs

Before dealing with recent work it will be profitable to consider on what kind of evidence these views of twenty years ago were based.

Evidence that fat is absorbed only after hydrolysis in the intestinal lumen was partly histological. Even at the height of fat absorption, fat particles could not be seen in the free border of the cells of the villi, though they were abundant in the body of these cells. It is, however, well known that fat may be present in cells and not be stainable as particles or globules, so that histological evidence by itself, which does not support the idea of fat being absorbed in a very highly emulsified state, is not conclusive. More convincing evidence was that, although fat-like substances such as esters of fatty acids are well absorbed, there is no evidence that this can be done without their previous hydrolysis by the lipase of pancreatic juice. For example, fatty acid esters such as cetyl palmitate, ethyl palmitate, and a lauric acid ester of mannitol are all well absorbed, but none of them appears unchanged in the fat of the chyle. What is found there is the glyceride of palmitic or lauric acid respectively.

Other information on this question had been got by feeding oily substances which were like fats physically but not chemically and were capable of being emulsified. It was found that they were completely unabsorbed. In this category come experiments with lanolin, mixtures of petroleum jelly and lard, or petroleum oil and olive oil. With the mixtures of natural fats and petroleum hydrocarbons the natural fat was absorbed but the petroleum product was not. The non-absorption of the petroleum was demonstrated either by its complete recovery from the faeces or by its non-appearance in the fat of the chyle.

Evidence, then, that fats could be absorbed only after hydrolysis to fatty acid and glycerol seemed fairly conclusive. But the problem of how fatty acids were absorbed even after hydrolysis still remained. The higher fatty acids are as insoluble as the fats and would still have to be absorbed from the fine suspensions or emulsions which were supposed to be present in the intestinal lumen, and histological appearances did not give any evidence that this actually happened. For this reason it had been suggested that the fatty acids formed soaps which, being soluble in water, could be absorbed in solution. There were two facts against this. First, it was believed that soaps are not formed at the faintly acid reaction of the upper regions of the small intestine. Secondly, even if soaps could be formed, there is not enough alkali secreted in the pancreatic juice to produce soap from the whole of the fatty acids which might be liberated from the fat taken at a normal meal.

The fact that bile salts will dissolve fatty acids, and, furthermore, the discovery that the lecithin normally present in bile assists this action very considerably, showed that a means existed whereby fatty acids could be brought into solution in bile and thus be absorbed in the dissolved state. There is ample proof, both from clinical findings and from animal experiment, that the presence of bile in the small intestine is essential to obtain the figure of about 90 to 95% absorption of fat which is normally found.

*Sharpey-Schafer Memorial Lecture given at the University of Edinburgh on May 19.

The effect of bile in promoting absorption might be due to its well-known adjuvant action on the hydrolysis of fat in the small intestine by pancreatic lipase. This would facilitate fat-splitting, and this was deemed a preliminary essential to absorption. But examination of the faeces in cases of biliary obstruction and consequent steatorrhoea showed that fat-splitting was not defective. Therefore, at the time I am considering, it was the solvent action of bile salts, potentiated by lecithin, which appeared to provide the explanation of the action of bile. Other possible ways in which the action of bile might be accounted for have been pointed out since; I shall deal with these later, for the mode of action of bile in promoting fat absorption is still a physiological problem. Nevertheless, at the time of which I am speaking, this solvent action of bile on fatty acids was accepted as solving the problem of how the insoluble higher fatty acids might be brought into solution and so absorbed.

Evidence that fatty acids when absorbed are resynthesized and appear as neutral fat in the lacteals was first provided by Immanuel Munk nearly 70 years ago. By collecting chyle from the thoracic duct of dogs to which fatty acids had been administered Munk found that the chyle contained not fatty acids but almost wholly neutral fat. He also showed some years later, in a human subject with a lymphatic fistula which discharged chyle, that after a meal including erucic acid the chyle contained only the glyceride erucin and not free erucic acid. Analyses of fat from the mucosa during fat absorption carried out by Moore about 50 years ago showed that this was a mixture of fat and fatty acids, and collection of chyle before it had traversed the lymphatic glands which lie along the course of the lacteals showed that the fat in these peripheral lacteals was almost wholly neutral. This indicates that resynthesis occurs in the cells of the villi.

It is interesting to recall that Munk, who had proved to his own satisfaction that free fatty acids were as well absorbed as neutral fat, believed firmly that the fatty acids were absorbed in a finely emulsified state. This was stoutly disputed by the indomitable Pflüger, but not, unfortunately, supported by any very satisfactory evidence, except the histological finding, already referred to, that fat is not detectable by staining methods in the free border of the cells of the villi. It was the discovery by Benjamin Moore of the solvent action of bile salts which to a large extent reconciled these opposite views and gave rise to what persisted as the classical view of fat absorption until a few years ago.

The Quantitative Aspect

There is one other aspect of these older experiments that I must deal with before proceeding to discuss later evidence on fat absorption, and that is the quantitative one.

The physiologist can be satisfied that what is termed the classical view of the process of fat absorption is true only if he can account satisfactorily for the whole of the fat absorbed. This has not yet been done. It would be thought to be a simple matter to collect the chyle from a thoracic-duct fistula in an animal during the whole period of the absorption of a meal containing a known amount of fat, but this has so far not been achieved. This is partly due to the inhibiting effect of general anaesthetics on fat absorption and to mechanical difficulties caused by frequent clotting of the chyle one is endeavouring to collect. Munk and Rosenstein, however, did succeed, using their patient with a lymphatic fistula in the leg, in collecting chyle for a period of 13 hours. After a meal containing 41 g. of fat, 1,134 g. of chyle were collected, and this contained 25 g. of fat—i.e., 60% of that administered. Although the chyle still contained fat, the experiment was stopped. Munk and his colleague assumed that, had the chyle been collected until fat was no longer present, an additional 6% of the fat administered might have been collected. This is the only quantitative experiment that has been recorded in which an attempt was made to give a balance-sheet accounting for the fat fed and that which passed into the thoracic duct. It has the obvious defect that the amount of fat actually absorbed was not measured. We know that olive oil is very well absorbed as a rule, and, assuming that all the chyle was being collected, for which Munk gave indirect evidence, we are left with the conclusion that about two-thirds of the fat absorbed reaches the thoracic duct via the lacteals, whereas the remaining third is unaccounted for. It has generally been assumed that it passes into the blood stream via the capillaries of the villi.

To sum up, the classical view was that fat was absorbed only after hydrolysis. The fatty acids so produced were absorbed dissolved in bile. They underwent resynthesis into neutral fat in the epithelial cells of the villi. This was then discharged into the reticular spaces of the villi and taken up by lacteals or blood capillaries. In the former case it entered the systemic blood vessels and in the latter it reached the portal blood and so passed direct to the liver.

Physiologists are perhaps more critical of classical views than are other scientists. It is not, therefore, a matter for surprise that the beliefs of twenty years ago have continually been questioned and subjected to further experimental inquiry. The result is that this classical view has been called in question and other possible mechanisms of fat absorption have been put forward.

Role of Phosphates

In 1934 Verzar and Laszt described experiments on rats which indicated that phosphates may play a part in fat absorption. Their method was to inject into the small intestine of the animals the mixtures they were testing and after six hours to withdraw them. The amount of fatty acid was estimated and compared with that introduced at the beginning, thus showing the magnitude of the absorption. There was practically no absorption when oleic acid alone was injected into the gut, but it was moderate when the fatty acid was mixed with bile acid or with bile acid and glycerol. It was nearly doubled when phosphate was added to the mixture. When glycerophosphate was used instead of phosphate then the absorption was increased still further. This suggested that esterification of glycerol by phosphoric acid may be an important factor in fat absorption.

It is known that the mucosa of the small intestine is one of the body's richest sources of the enzyme phosphatase, so that in the presence of phosphate the glycerol split off from fats in the process of digestion might undergo conversion to glycerophosphate in the cells of the villi.

Furthermore, it was shown that mono-iodoacetic acid, which inhibits the enzyme phosphatase, also inhibits the absorption of fatty acid. But this inhibition of fat absorption is still evident when the fatty acid is mixed with bile acids and glycerophosphate, so that Verzar concluded that the iodoacetic acid acts by preventing in some way the resynthesis of neutral fat in the mucosal cells rather than by preventing phosphorylation. It was shown in Verzar's laboratory that the action of lipase was not hindered by iodoacetic acid, so that a failure to hydrolyse fat did not

explain why the fat was not absorbed after administration of this substance. What seems most likely is that its action as a general cellular poison is a sufficient explanation of its prevention of fat absorption.

Verzar showed also that phlorizin prevented fat absorption in rats. This substance also inhibits the enzyme phosphatase. The doses that have to be used are very large and the complete inhibition lasts for only a few hours. Nevertheless, these experiments are more suggestive than those with iodoacetic acid that phosphorylation is an accelerating factor in fat absorption. Histological observations from Verzar's laboratory indicate that it is not the entry of fatty acids into the cells of the mucosa which is prevented, but rather the resynthesis into neutral fat and its transport away from these cells. Thus, staining methods which differentiate fat from fatty acid show that a few hours after administration of iodoacetic acid or phlorizin most of the globules or particles inside the cells of the villi consist of fatty acid, whereas normally they would be neutral fat.

If phosphorylation is an important aid to fat absorption by the villi, it probably indicates that the synthesis of lipins is an intermediate stage in the resynthesis of neutral fat.

There is, however, not much more experimental evidence on this point. Examination of the fat in the chyle has shown that it does contain a small amount of lipin, but the proportion does not exceed 10% of all the fat present.

Estimations of the lipin content of the cells of the villi during the absorption of cotton-seed oil in pigs have also been made by Reiser, but have shown no change within five hours. It has also been shown by Barnes, Miller, and Burr in rats fed with a methyl ester of the conjugated acids of corn oil, which can be estimated by spectrophotometric methods, that at a time when the absorption was maximal there was only a slight incorporation of the fatty acids administered into the lipins of the cells. This indicates that if lipin formation is essential in fat synthesis in the cell the rate of transformation of lipins into neutral fat must be very rapid.

Experiments in which phosphate containing radioactive phosphorus has been fed along with fat have shown that the isotopic phosphorus becomes incorporated in the lipins of the mucosa. But this does not provide evidence of new formation of lipins during fat absorption, because the isotope might have undergone exchange with the phosphorus of the pre-existing lipins.

We must therefore, I think, come to the conclusion that the facilitation of fat absorption by phosphate and glycerophosphate, which was demonstrated in rats by Verzar and his colleagues, has not yet led to an explanation of the mechanism by which it is brought about. The study of the lipins in the mucosa during fat absorption has certainly not given one.

The Partition Hypothesis

Other experiments which I wish to describe next have been concerned to a large extent with the fat in the blood and its relation to the processes of fat absorption. It is well known that during the absorption of fat the blood plasma has an opalescent appearance. This is due to the presence of fat in extremely fine suspension.

Under dark-ground illumination the microscopic particles of fat appear as points of light and can be counted. A method for estimating their number under standard conditions was described about ten years ago by Frazer and Stewart. The particles are called "chylomicrons," and the number present under these standard conditions we may refer to as the chylomicron count. The graph representing the change in this count with time is spoken of as a "chylomicrograph." It is obvious that unless the chylomicrons are always of the same average size a mere estimation of their number would not give an accurate indication of their weight. If, therefore, the chylomicrograph is to be used to indicate the relative amounts of fat in the blood at different times, then it must be known whether under all conditions the fat content of the blood runs parallel to the chylomicron count.

A study of the results published from Professor Frazer's laboratory shows that the count is very low during starvation, and that it rises considerably after a meal which contains fat. There is a peak about three hours after the meal. When the fatty components of the blood are estimated and the amount is compared with the count there is a rough parallelism between the two with glycerides, but not with lipins and cholesterol esters. It must therefore be borne in mind that the chylomicrograph gives no more than a qualitative indication that the amount of fat in the blood varies under different conditions. It does not allow us to estimate either the percentage variation or the absolute amount present under those different conditions.

Nevertheless, the study of chylomicrographs in relation to fat absorption has revealed several interesting facts which require explanation.

Rats were given some olive oil or the equivalent amount of oleic acid and glycerol. After olive oil the lacteals appeared milky, and the chylomicron count in the systemic blood was high, but in the portal blood it was low. With the oleic acid and glycerol the chylomicron count in the systemic blood was low, whereas that in the portal blood was high and the lacteals were relatively free from fat.

These findings suggest that in the rat, at all events, neutral fat and fatty acid are dealt with differently in the process of absorption. Additional evidence for this view was obtained by feeding stained fat or fatty acid to rats. After a week of such feeding the fat depots were deeply stained when stained fat was fed, but were not when equivalent amounts of stained fatty acid and glycerol were given. Furthermore, if rats were fed with small quantities of stained fat or fatty acid and killed five hours later the liver showed only a small amount of stained fat after feeding with fat, but a large amount after feeding with fatty acid.

From these and other observations Frazer concludes that neutral fat is absorbed direct into the intestinal cells and is passed on without change to the lacteals. On the other hand, fatty acid is absorbed into the cell by a different mechanism. It is passed into the blood capillaries of the villi and reaches the liver in the portal vein.

According to Frazer, therefore, lipolysis is *not* an essential preliminary to absorption, and neutral fat and free fatty acid can both be taken up by the intestinal cells. When they are taken up they are treated differently.

The view that some of the absorbed fat might be taken up by blood vessels in the villi and not by the lacteals does not conflict with previous evidence. It will be remembered that in Munk's quantitative experiments with the patient who had a lymphatic fistula about one-third of the fat administered was not accounted for by passage into the lacteals, and it has therefore been assumed that the pathway of this fat was the blood vessels of the villi.

What is new about the deductions drawn by Frazer and his colleagues from the comparisons they have made between the absorption of fat and fatty acids is that an unspecified amount of the fat which is absorbed in the

rat when neutral fat is administered is absorbed without previous hydrolysis in the intestinal lumen.

Histological Picture

In addition to the evidence obtained from chylomicrographs and the appearance of the lacteals, Frazer and his colleagues have drawn attention to the different histological pictures presented in the small intestine when olive oil and oleic acid are administered. With olive-oil feeding the cells are mostly occupied by large globules of fat, whereas when oleic acid is given the cells are full of much smaller particles, presumably of the fatty acid. Frazer makes the point that if fat-splitting must precede fat absorption then administration of fatty acid should produce the same histological picture as administration of neutral fat.

It is, however, a legitimate comment on this view that one might not necessarily expect to get the same histological appearances, because the conditions are not the same. In the case of olive-oil feeding, the fatty acid is liberated gradually and therefore in small concentration; when fatty acid is fed it is presented to the cells in maximum concentration ready formed. In the latter case the cells are, so to speak, swamped with fatty acid, but in the former case they may be able to deal with it in a more leisurely manner. This is the old problem of histology. To what extent are we justified in interpreting dynamic functions from static pictures? I feel that it is unsafe to draw fundamental conclusions on fat absorption from histological evidence of this kind alone.

Frazer, however, has obtained other evidence in support of his view that in absorption fat and fatty acid are treated differently by the intestinal cells.

The rate and amount of lipolysis in the intestine can be increased by adding an active preparation of lipase to the fat which is fed. When this is done in rats, the histological picture is like that obtained when a fatty acid such as oleic acid is fed—i.e., the cells are filled with fine granules. The path of absorption is also like that observed with fatty acid feeding—namely, absence of milkiness in the lacteals—and when stained fat is given along with the lipase the liver is deeply stained but not the fat depots. In addition to these observations it is found in man as well as in the rat that addition of lipase to the diet causes a considerable change in the chylomicrograph. At the peak period the chylomicron count obtained when fat is fed greatly exceeds that which results from feeding the same amount of fat with added lipase.

The reverse of this experiment has also been carried out by Frazer. This was the inhibition of the action of lipase of pancreatic juice by giving a small amount of sodium cetyl sulphate with the oil fed. This prevents the hydrolysis of fat by lipase and, in the rat, produces a histological picture like that obtained with neutral fat alone—namely, intestinal cells filled with large fat globules. Along with this the lacteals are found to be milky, and when stained fat is fed along with cetyl sulphate the fat depots are heavily stained, whereas the liver is not. This again points to lipolysis not being essential for fat absorption and different paths of absorption being followed by fats and fatty acids. In Frazer's experiments with cetyl sulphate it seems likely that inhibition of lipolysis was almost complete. That fat was absorbed in amounts which were quite normal was attributed by him to the emulsifying action of cetyl sulphate, which would be expected to produce fine particles of fat in the intestinal lumen. These could be taken up directly by the intestinal cells if his view is correct.

To my mind these experiments with cetyl sulphate provide the best evidence that has yet been put forward that, in the rat at all events, fat may be absorbed without hydrolysis if it is finely enough emulsified. Cetyl sulphate is a particularly valuable tool because, besides its surface active properties, it inhibits lipase. The fine emulsion it produces would normally lead to a more rapid action of lipase, and hence production of fatty acid. But this being prevented enables the effect of emulsification alone to be studied.

Emulsification

Emulsification, its degree of fineness, and the conditions which bring it about are very important in fat digestion and absorption. I should therefore like to say more about them at this stage.

Because fat is insoluble in water its digestion takes place at the interface between the fat globule and the surrounding medium which contains the fat-splitting enzyme. The more finely divided the fat—i.e., the more it is emulsified—the greater will be its surface area and, other things being equal, the more rapidly will it be split up into fatty acids and glycerol. According to Frazer, fine emulsification is also a prerequisite for absorption of fat in its unchanged state. It is clear, therefore, that in the small intestine there will be two competing processes for disposing of the fat which enters it from the stomach. The more finely the fat is emulsified the greater will be its chance of being split up into fatty acid and glycerol, both of which can be absorbed in solution. But, also, the greater will be its chance of being absorbed in particulate form.

We have as yet no answer to the question how much of the fat travels by what we may call the fatty acid route and how much is taken up as neutral fat. It is, however, obvious that whatever proportion, if any, is absorbed in particulate form depends almost entirely on the existence of conditions in the intestine which will facilitate the production of a very fine emulsion.

This leads us to consider what those conditions are. We are again indebted to Professor Frazer and his colleagues for some experiments that have thrown a great deal of light on them.

There is general agreement that the reaction of the contents of the small intestine varies between a *p*H of about 6.5 and 8.5. A prerequisite for particulate absorption of unchanged fat is therefore the existence of a stable, finely divided emulsion between that *p*H range. It has been shown by Frazer that, if olive oil is placed in a rat's stomach and the animal is killed three to four hours later, its small intestine contains a white emulsion of fat consisting of negatively charged particles less than 0.5 μ in diameter. The emulsion is stable for several hours.

This shows that administration of oil does provide the kind of emulsion that would be required for particulate absorption. By studying systematically the emulsifying effect on olive oil of single, paired, and triple combinations of bile salts, oleic acid, soap, glycerol monostearate, and soap formed at the oil–water interface by the reaction between oleic acid and sodium carbonate, Frazer and his collaborators found one triple combination that provided the requisite kind of stable emulsion. It consisted of bile salt, oleic acid, and glycerol monostearate. The oleic acid and monostearate were dissolved in the oil and a 1% solution of bile salt formed the aqueous phase. On mixing, emulsification was spontaneous over the *p*H range 6–8.5, the particle diameter averaged less than 0.5 μ, and the stability was all that could be desired.

It is not difficult to produce emulsions of fat in an alkaline medium, but it is when the reaction is even slightly acid, as in the duodenum; hence the special importance of this new discovery by Frazer. If this sort of combination is that used normally in the intestine, it implies that a stepwise hydrolysis of fat takes place with monoglyceride as at least one of the phases. I am not aware of any demonstration that when lipase acts on fats the three component fatty acid molecules are split off one at a time, although this might well be so. In fact, the only difficulty in accepting this three-component system as one which may be responsible for emulsification in the small intestine is the lack of experimental evidence that a monoglyceride stage exists as a phase in the action of lipase on fats. There seems to be no theoretical objection to this, so possibly in the future we may expect to see some proof of it by experimental means.

Importance of Bile

It will be observed that this work on emulsification provides a new function for bile salts and therefore emphasizes the importance of bile in the digestion and absorption of fat. All the following functions may be attributed to bile salts. In digestion they have two roles: besides increasing the surface area by aiding emulsification of fat they have an adjuvant effect on lipase itself, speeding up its action several times. In the process of absorption they are believed to play several parts. One of these is to dissolve fatty acids, probably by forming soluble complexes with them.

Wieland and Sorge have shown that one of the bile acids —deoxycholic acid—forms definite compounds with fatty acids, the so-called choleic acids. They have suggested that these acids, coupled with glycine or taurine, may therefore play a part in enabling fatty acids to enter the intestinal cells. Verzar and McDougall suggest that bile salts form a layer at the surface of the intestinal cells, where they produce water-soluble and diffusible complexes with fatty acids and so assist the entry of the latter into the cells. Finally, according to Frazer and his collaborators, they are necessary for producing the stable emulsions of fat with particles less than 0.5 μ in diameter and capable of existence in a *p*H range of 6–8.5 which are postulated as necessary for particulate absorption of fat.

In spite of this variety of ways in which bile salts assist fat absorption, they do not seem to be absolutely essential. It is one of the interesting problems of absorption why they are not.

The most trustworthy evidence for this comes from experiments on dogs in which a biliary fistula had been established. Munk has described how in animals treated in this way and fed on diets containing varying amounts of suet or lard, or, alternatively, with the fatty acids derived from them, a considerable amount of the fat or fatty acid was absorbed. The figures for the quantity of fatty acids taken up during the passage of the food through the intestine were always a little higher than those for the corresponding amount of neutral fat. Also, the lower-melting fat was absorbed better than the higher-melting one. Thus lard was absorbed to the extent of 67% and suet to 35% when the daily intake was 70 g., the corresponding figures for the fatty acids being 73% and 42%.

Other experiments on human subjects with biliary obstruction bear out these results. Schmidt, for instance, describes the findings on three cases in which the average fat utilization was 74%. In two of these the obstruction was complete.

These results leave no room for doubt that although the presence of bile in the intestine assists fat absorption it is by no means essential.

In the experiments of Frazer and his colleagues on emulsification the only stable emulsion obtained at the *p*H found in the upper part of the small intestine was obtained in the presence of bile acids and monoglyceride. These, however, could not have been present in the experiments of Munk on the absorption of fatty acids, which I have just described. It seems a reasonable conclusion, therefore, that large amounts of fat and fatty acid can be absorbed under conditions which do not fit in with those so far shown to be necessary to produce fine emulsions at the slightly acid reaction of the intestine.

I have pointed out earlier that the solvent action of bile for fatty acids was the one property which led to the abandonment of the particulate absorption theory about fifty years ago. Since so large an absorption of fat or fatty acid can take place in the absence of bile, we are led to the conclusion that some other solvent for fatty acids must be present or that some undescribed emulsifying system exists which can explain the remarkable degree of absorption obtained when bile is absent. It is important to bear in mind that the diet used by Munk in his experiments was a mixed one and contained a large proportion of meat. Possibly digestion products of protein and especially amino-acids in high concentration may assist in emulsification, or in stabilizing emulsions, or in actually combining loosely with fatty acids so as to assist their absorption. This must remain a speculation, however, until experimental evidence about it can be obtained.

Absorption of Paraffin

One other set of recent experiments on the absorption of oil emulsions is of importance. It is the work of Frazer, Schulman, and Stewart on the absorption in the rat intestine of emulsions of paraffin. These observers found that 50% emulsions of liquid paraffin stabilized with cholesterol and sodium oleate or sodium cetyl sulphate could be prepared with an average particle diameter of 0.5 μ or less. These when introduced direct into the rat's intestine were absorbed to the extent of 36 to 43% in a period of six hours. It will be observed that no bile salt was used in making these emulsions, so these experiments show again that bile is not essential for absorption of fine emulsions. With coarser emulsions, in which many particles had a diameter of 1 to 2 μ or more, the absorption was very much reduced.

These experiments show that, provided an oil emulsion is finely enough dispersed, it can be absorbed in the rat's small intestine. Some alarm has been expressed on this account at the use of medicinal paraffin as a medicament and in cooking. It has been suggested that if paraffin is absorbed it would tend to accumulate in the body in undesirable situations, since it is not oxidizable, or, if it is, then only with great difficulty. So far as I am aware, no evidence has been produced that the fine dispersion of paraffin which Frazer and his colleagues have shown to be necessary before absorption can take place is obtained when the oil is taken by mouth in the normal way. On the experimental side it may also be recorded that Channon and Collinson many years ago gave 100 ml. of emulsified paraffin daily to a pig for 54 days. On extraction of the fatty substances from its liver 2.2 g. of unsaponifiable material was obtained, which was possibly derived from the 5.4 litres of oil that had been administered. This does not suggest that absorption of paraffin takes place in an amount that would be of material importance.

Steatorrhoea

A final topic that must be considered briefly is whether diseases involving defects in fat absorption have taught us anything about the physiology of the process. In certain fields of physiology it is true that a study of disease has helped to throw light on physiological processes, but that can hardly be said of disorders in which fat absorption is at fault. It is true that biliary obstruction causes steatorrhoea, but that fact has not explained the reason why. Similarly, pancreatic disease, or in extreme cases complete pancreatic obstruction, interferes with fat absorption.

Those who uphold what I have termed the classical view of the mechanism of fat absorption would state that this was due to defective hydrolysis of fat caused by the partial or complete deficiency of pancreatic lipase. That would seem to be a satisfactory explanation. At first sight it also counters the modern view that fine emulsification is all that is necessary in order that fat absorption may take place. But we have to remember that the failure of both bile and pancreatic juice to enter the small intestine may result in the non-production of the necessary conditions for that fine dispersion of fat which is regarded as essential for its absorption. Hence the faulty absorption which is associated with diseases of the pancreas and bile ducts has not helped in explaining the mechanism which we wish to have made clear.

Another disease in which steatorrhoea occurs is tropical sprue. I am indebted to my colleague Dr. D. A. K. Black for his views on the defective fat absorption which is a well-known sign in this condition. First, there is no evidence of a selective failure of fat absorption. The steatorrhoea seems to be part of a general impairment of absorption. This in itself does not help us in our search for the true mechanism of the absorption process. Secondly, the percentage absorption of fat does not vary with the amount of fat in the diet. In five patients, for instance, whose daily fat intake was increased from 65 g. to 95 g. the percentage absorbed did not show any significant change. This does give a clue to the kind of mechanism which is involved. The defect cannot be a purely physical one, otherwise the absolute amount of fat absorbed would not depend on the quantity in the diet. Thus some biochemical defect, such as one in the enzyme systems concerned in fat absorption, is indicated. It is interesting that Munk, in his studies of fat absorption in dogs, in the absence of bile found a similar relationship to hold, provided that the normal capacity for dealing with fat was not exceeded.

A third discovery which Black and his colleagues made is in harmony with the view that the defect in tropical sprue is a biochemical one—that is, that administration of yeast extract in this condition has a favourable influence on fat absorption. This suggests that some accessory food factor is possibly lacking. Apparently it is not nicotinic acid, riboflavin, or folic acid. Its identity, therefore, if there is any truth in this suggestion, still remains to be discovered.

Conclusion

Perhaps I have said enough to show that I regard the processes of fat absorption as still not completely understood. The intelligent use of some of the new isotopes which the physicists are now putting into our hands could undoubtedly help in solving some of the outstanding problems, and I hope that in due course these new methods may be made use of. I can certainly commend to any young physiologist the study of fat absorption as well worthy of his attention.

MODERN TRENDS IN RADIOLOGY*

BY

JAMES F. BRAILSFORD, M.D., Ph.D., F.R.C.P. F.I.C.S.

Director of Radiological Studies in Living Anatomy, University of Birmingham

In this paper it is my intention to stimulate thought by taking stock and critically examining the prevailing tendencies and so obtain a perspective which will enable us to see where we are going.

The radiological age may be divided into three periods —(1) that which heralded the advent of radiology; (2) the period of distrust; (3) the period of idolization—the modern trends.

When Roentgen's remarkable discovery was made known to the world, the Press (Brailsford, 1946a)—both medical and lay—heralded it as a means of sparing patients not only the pain associated with disease but also that which was, and still is, inflicted when other methods of examination are conducted. First impressions are often the most important and deserve the fullest consideration, and these first impressions were so strong that they stimulated radiological research throughout the world to such a degree that during the year 1896 most of the possibilities of radiology were envisaged, techniques developed, and explorations begun. Continuous progress since then has been essentially refinement of technique, concomitant with ever-improving equipment. Unfortunately many enthusiastic workers in the earlier years did not preserve the scientific accuracy in their observations that is so essential for progress. Because interpretations were read into radiographs which were far in excess of what was reasonably possible —a tendency which has not been entirely overcome—clinicians were taught to distrust radiology; but the more careful workers in radiology, by painstaking study of the normal and by correlation with pathology, convinced clinicians that they could render much help in the elucidation of clinical problems. Some radiological evidence is self-explanatory even to the layman, and this has resulted in the misconception amongst the inexperienced, both qualified and unqualified, that all radiographs are self-explanatory. In the light of the previous high standard of clinical medicine it is amazing that this serious misconception,

*An Address given at a Special Meeting at the College of Physicians of Philadelphia, October 22, 1948, and later at other University Medical Centres of the United States.

associated as it is with the five following very remarkable omissions, should have been allowed to prevail.

Omissions in Medical Practice

(1) Failure to realize the importance of, and to carry out, a thorough clinical examination before any radiology—radiology being regarded as an easily obtained substitute requiring little personal effort. On the serious errors in diagnosis and treatment which this has occasioned a great deal could be written. Careful attention to the clinical condition of the patients in these cases would have spared them much mental and physical pain, and the clinicians the blame the fruits of which they escape perhaps too often. There would be fewer errors in the interpretation of radiographs if radiology was always preceded by a sound clinical examination: if one of these must be omitted the least harm will come from omission of the radiography and most from omission of the clinical examination.

(2) There has been a failure to learn the bounds and appearances of the normal, and even the character of the artifacts produced by faulty material and techniques. Radiographic methods have been applied to the examination of structures made visible by contrast media, and operations have been conducted to remedy "defects" long before the appearances of the normal have been learnt: when sound knowledge of the normal has with time and experience been acquired the operative measures for the correction of some of the "defects" have been abolished. This was very noticeable in gastro-intestinal radiology. I am confident that in the realms of other specialties, notably thoracic surgery and neurosurgery, the same sequence will occur, for in these our knowledge of radiology, with and without contrast media, is still inadequate and incomplete; yet surgical explorations based upon the radiology are many.

(3) It is often not realized that the initial changes in many conditions are indistinguishable from one another, and that serial radiographs with continuous clinical examinations over a short or long period may be necessary for elucidating a problem.

(4) Many have failed to appreciate that the onset of disease is not associated with immediate changes in the radiographic appearances, and that it requires time—what I have called "the latent negative radiographic period," sometimes only a few days, but sometimes a year or more (Brailsford, 1946b)—before the changes are sufficient to produce enough contrast density or irregularity of contour to alter the radiographic appearances from the normal: by the time these changes are recognizable they are extensive—in some conditions more extensive than the radiographs suggest—in some cases healing may have commenced. Even fractures and other more serious conditions of bones and joints may be masked, if displacement has not resulted, until secondary changes have developed.

(5) There has been a failure to realize that, though the disease has ceased its activity, the radiograph may show spectacular appearances even to the end of an apparently normal life—the positive radiographic symptomless period. It is questionable whether surgical measures with their attendant risks would be so often undertaken if the full importance of this were understood. In some cases failure to appreciate omissions 4 and 5 have, on the other hand, led to the disregard of active clinical signs or recent injury when radiographs have shown no sign of change or only the typical evidence of old healed lesions. You may ask what evidence I have of these omissions. I believe you could obtain such evidence from the activities in many hospitals, but the strongest evidence is in the boosting of mass radiography.

Mass Radiography

I have recorded elsewhere (Brailsford, 1945a, 1948a) the serious limitations, erroneous interpretations, and liabilities of mass radiography and the relative poverty of its contributions to preventive medicine. Undoubtedly it has an important propaganda value, but it is the propaganda of fear by which the public—yes, and the medical students—are being frightened into the erroneous belief that active progressive disease is symptomless and only the radiograph can reveal it. It can be proved to have been responsible for the infliction of much unnecessary mental and physical pain.

Mass surveys are essentially bureaucratic regimentation measures designed by officials and enthusiasts who appear not to have the knowledge of the five omissions or the experience to judge the efficiency of the measures adopted, and, while they themselves are spared the rigours and anxieties of the general practitioners attending to the sick, would decry the contributions of these latter doctors to the reduction of the incidence and mortality from tuberculosis. Mass radiography has not added anything new to our knowledge of radiography of the chest. The evidence obtained by it has been used to re-emphasize the fact that about 4 per 1,000 of the population have signs of active tuberculosis; but not enough importance has been placed on the other confirmatory evidence it has yielded —i.e., that at least ten times as many persons, or 40 per 1,000, have had fairly extensive disease and recovered from it without knowing of its existence and in most cases without having lost time from work. Had radiography been applied to all these at the stage when the appearances suggested activity it would have inflicted on them the dreaded stigma of tuberculosis and seriously interfered with their lives without contributing any good. A little reasonable education in hygiene would have accomplished much more, at less expense in money, equipment, buildings, personnel, and above all in feelings.

Because there would appear to be conditions of medical service which permit certain cases of pulmonary tuberculosis to be overlooked by medical officers is an indication not that the progressive disease is symptomless but that the clinical examinations are poor; for when such patients return home the diagnosis is made by the parents, confirmed as grave by the general practitioner, and registered as deadly by the consultant a few days before death. The greater the percentage of cases of unknown progressive tuberculosis discovered by mass radiography, the poorer the clinical medicine that has been applied.

Spectacular radiographic evidence of tuberculosis, as well as other conditions, may persist for many years, during which it is symptomless because it is quiescent or healed and of little importance from the point of view of infection. The most successful surgical results have been obtained in cases which have previously healed themselves and are symptomless. Reversal of the radiographs —i.e., showing the last in the series first and the first last —is worth doing, for it will often indicate what appears to be a miraculous cure, particularly when the series includes a number of radiographs taken at intervals in the early days, during which no change occurred prior to the surgery.

I find it difficult to reconcile the views of modern clinicians on tuberculosis. If one examines the serial post-operative radiographs, tries to evaluate the risks run by the patients, and compares the end-radiograph with the

one which incited the surgery, one finds it difficult to believe that the latest radiograph satisfies, or that it justifies the measures adopted. If the inciting radiographic features were unaccompanied by signs and symptoms these post-operative radiographic appearances of mutilations are certainly not without them. There would appear to be no more justification for removing a healed or quiescent lesion of the lung (which would not have been suspected if there had been no radiograph) than of any other structure, or in fact for removing any normal tissue; since valuable healthy lung is removed.

Though patients derive great benefit in those sanatoria where mental and physical rest, good fresh air, and food are the essential characteristics of treatment, they have to return to the debilitating influences of the poor home which broke down their resistance. The best place to treat tuberculosis is the home, and only those efforts which are designed to make the latter fit for living in are likely to cut out tuberculosis effectively and permanently. The best preventive medicine is that aimed at prevention, not that which is aimed at treatment of disease that could have been prevented. The lack of sincerity and fairness in this propaganda is shown in the recent report of the Brookings Research Institute, which states that tuberculosis is three times more prevalent in coloured than in white people and syphilis six times more common. The unfortunate individual labelled as tuberculous is subjected to all the disadvantages which the stigma of this disease brings—i.e., inability to insure, estranged social and business contacts, and other serious interferences with life and liberty; whereas the stigma of syphilis, the loathsome contagious disease to which innocent persons can be subjected, is treated with all privacy, though with effective measures it could be stamped out.

Radiography and Clinical Medicine

In spite of all these drawbacks to mass radiography of the chest I believe it could be used for the groups I have enumerated. But there are signs that the degeneration of clinical medicine is spreading with the aid and at the expense of radiology: it will ultimately bring radiology into disrepute. In a recent English newspaper it was stated that "one in every 20 people in Britain—or over 2,000,000—suffers from rheumatism. So it has been decided to mass-radiograph the joints of groups to ascertain the extent of the disease. When the unit is in operation it is proposed that every one of the 73,000 miners in the area will be *x*-rayed whether he has rheumatism or not." As pointed out by an orthopaedic surgeon in a letter of appreciation of my opposition to this type of activity, "The whole thing is really an attempt on the part of some people to increase the number of attendances of their patients to astronomical figures and to increase similarly the work of other departments, and on the strength of this to increase the number of staff. The result of this is, of course, that with a very large staff the man in charge must be a very great person."

Mass radiography of the stomach is being used in one famous American hospital (surprisingly enough, in one to which a former physician brought great fame by his contributions to clinical medicine) for the detection of early malignant disease, and claims have been made of tests which reveal its presence. This might well incite further extensive mass radiological investigations. I believe one's energies in this direction could favourably be reserved until a cure for malignant disease has been discovered; then it could be applied enthusiastically with all skill.

There are other spheres in which the use of radiology not only fails to spare the patient pain but actually incites the infliction of pain by the performance of investigation including surgery, which can be regarded as little else tha meddlesome. I heard a professor of medicine at one c the universities urge that ventriculography was a usefu harmless, and painless method of investigating the cau of headaches. I saw the exhibition of radiographs of patient with three aneurysms of the aorta, one of whic showed radiographic evidence of erosion of the sternu and ribs. This patient sought the doctor because he ha pain, and it should be our first duty to relieve that pain yet this evidence did not incite the observer to pity, bu to inject the aneurysm with opaque media to provide spe tacular evidence of the extent of the lesions—knowledg which could not be of the slightest use to the patient, bu which apparently satisfied the callous inquisitor.

Radiology in the Curriculum

Radiology is being brought increasingly into the medica curriculum. Unfortunately, I repeat, its chief use appear to be to obtain quick answers with the least effort on th part of those demanding it. It has been brought into th study of anatomy. Instead of realizing that it merely give additional information, and in no way diminishes the nee for training in the dissecting-room, we find the hou devoted to anatomy and the basic science being reduce to provide time for specialized subjects. Students are bein taught to be "scientists" and not doctors. The truth of thi is seen in the difficulty in getting young men to practis in the country, where they have not at their elbow *x*-ra equipment and laboratory services, on which they have bee taught to depend. To provide them with these facilities i not the answer for good clinical medicine, since their train ing in this has been ineffective and in these specialize fields but superficial. Recently I was amazed to hea that a medical student, induced by a spectacular film o rehabilitation to give up the doctor's course and take u physiotherapy, had been told by the Physiotherapy Societ that the university course in anatomy was not of a suffi ciently high standard to permit of exemption from thei preliminary examination in anatomy. Surely the medica course ought to be superior to that used by any auxiliary medical services, for the work of the latter must neces sarily be under the direction of the doctor, and any con tribution which radiology makes to this down-grading in training should be eliminated. I know that radiologists are called upon every day to demonstrate not less bu more anatomical structure, and we do it at the demand of the clinician. More attention to anatomy may deprive the student of hours of specialized scientific research. but it might spare him (and the patients) the pain expended in unnecessary investigations of little use in treatment.

At a recent discussion on the role of radiology in the teaching of anatomy it was stated that, while it was reasonable to give students barium meals and allow their colleagues to study the passage throughout the alimentary canal, it was not considered reasonable to allow their colleagues to inflict barium enemata upon them. I urged that as a teacher I felt it was a duty to teach the subject in a manner that the students would not forget, and therefore it might be a good thing if they performed upon one another every type of injection, including ventriculography, myelography, arteriography, etc. In this way they would be taught in an indelible manner by the unskilful hands of their colleagues just what such examinations mean to the patient. It might cause them to consider the patient and to insist on skill and the reservation of such investigations to the last resort, after all other investigations hac

been made and it could be reasonably thought that such investigations would be of value.

If after a thorough clinical examination by an experienced clinician, assisted by such plain radiography as that indicated, it is thought that injection of opaque media would help in the treatment of the patient's condition, I am of the opinion that that injection should be done by the clinician desiring the information—presuming, of course, that the latter has sufficiently studied the technique and acquired the necessary skill. It is probably on the evidence so obtained that operative or other treatment will be employed; therefore it must be done with every care and with skill, recognizing the great responsibility. Too frequently it is left to inexperienced house-men, as will be seen from radiographic studies of the results; these are often vitiated by faulty techniques unskilfully applied and therefore useless. Such injections should not be given merely to obtain "a pretty picture" or to satisfy curiosity, for they are done at the expense of mental and physical pain and unknown risk to the patient, who has come to us trusting in our faith and high calling to relieve pain. Scientific data are too frequently sought at the expense of human and animal pain and sacrifice. In the long run this action can result in atrocities, cruelties, or licensed murders, as we have learned from the report of Czechoslovak doctors on medical atrocities in prison camps. Little credit is due to those who would "wade through slaughter to a throne, and shut the gates of mercy on mankind."

By radiography we can now ascertain the nature of the majority of bone tumours (Brailsford, 1948c); we can say whether they are due to developmental irregularities, deficiencies, or endocrine disorders, to trauma, inflammation, or neoplasm. Regarding the last-named, we can recognize the usual simple tumours, and by serial radiography and continuous clinical observation determine in a large proportion of such cases whether malignancy exists. All this we can do without inflicting any pain, and the more attention we pay to such radiography the fewer will be the cases which we fail to diagnose. There is a modern tendency to cut down and explore every bone tumour. Spectacular radiographic appearances are allowed to incite this activity even when they are discovered accidentally during other investigations, and such radiography is doing more harm than good. There seems to be a widespread erroneous belief that the last word in the diagnosis of bone tumours can be obtained by histological examination. We can show (Brailsford, 1948b) that, given adequate study, radiology offers greater accuracy and that the infliction of biopsy with all its risks is unnecessary and of little value.

Radiology is a whole-time study, and the careful radiologist will discover something new each day, so infinite are the variations of and departures from the normal. To say that we have not seen a certain thing, and by so doing imply that it does not exist, is not a testimony to great experience but a confession of ignorance. The chances are, as my experience shows, that within a few days or weeks an example or examples of such a condition will occur in practice, and many more will probably be found in the literature. In a previous paper (Brailsford, 1945b) I have recorded the abuses to which radiology is put; they still continue.

A Modern Tendency

There is a modern trend for the members of various specialties to gather together and seclude the radiographs illustrating conditions with which they deal, and the *x*-ray departments and hospitals are so much the poorer because this valuable material is lost to the general use of the hospital and the special use of the radiologist. Radiology knows no bounds of specialization. The radiograph is a measure of the relative density and a record of the contrast outlines and structures of all tissues on and between the two skin surfaces which bound the area. We therefore need radiologists who understand all the evidence presented to inspect the whole, for there is a tendency on the part of specialists to be obsessed by evidence which appears to involve their specialty. Only good can come from whole-hearted co-operation, but harm will result to patients from seclusion and isolated activities, for which the responsible person may be called upon to bear the blame.

Requests for *x*-ray examinations are made on forms which have a space with some such heading as "Conditions revealed by the clinical examination on which radiological evidence is required." Those clinicians who co-operate and desire all the help which the radiologist can give, the men who really taught me my radiology, fill in this space with facts gleaned from the clinical examination that are invaluable to the radiologist. Those men who ape a knowledge of radiographic technique and want the radiographs, but no assistance otherwise, use this space for giving instructions with certain cryptic signs, designed to impress the radiologist with their great knowledge of radiographic technique, such as, "A.P. and L," and if they wish to display their profound knowledge they add also, "P.A. and oblique." Such requests fail to convey any suggestion of confidence in the radiologist, and certainly do not invite him to share the responsibility; consequently he loses the stimulus for good work and the patient suffers accordingly from the defective interpretation of the radiographs.

Radiography, together with other ancillary services to clinical medicine, is being used extravagantly and is one of the chief contributors to the increased cost of medical service.

An American Experience

During my tour of the United States I went into one large department and was shown the latest and most expensive equipment operated in conjunction with a photo-electric cell, the latter replacing the brain of the technician. The films were processed in an automatic developing unit, from which they issued as a finished product. I asked to be shown the next unit, and in reply to the question, "What is that?" gave the answer, "The machine for turning out the reports." "Take a seat and wait a few minutes," I was instructed; "I think we can show you that." A junior member of the staff appeared a few minutes later, took out a stamping-machine from a cupboard, and began to stamp a large pack of reports. One of these was handed to me with the remark, "Does that satisfy you?" The report sheet with the name of the patient had been stamped with the report "Normal" and the radiologist's signature. On inquiry I was told that about 80–90% of the reports were of this nature. I said, "Now, this is interesting, for I have just come from San Francisco, where the President of the North American Radiological Society gave an address in which he said that three of the leading radiologists of America had examined a large series of radiographs and their reports showed a difference of opinion amounting to something like 30%." I asked whether it would not be better simply to stamp all the reports "Normal," for then we should have a discrepancy of only between 10 and 20%; or would it not be advisable to avoid radiology

entirely owing to its expense: probably the best thing would be for clinicians to use radiology intelligently and thus cut down hospital expenses and treatment of the patient.

Radiology an Aid to Study

It is thought, by those least qualified to judge, that radiological knowledge is now so general that there is no need for anyone to specialize in radiology. But is not clinical medicine or surgery a full-time study, leaving little or no time to acquire adequate knowledge of radiology? I would remind you of the valuable contributions which were made to medicine and surgery before the advent of radiology, when clinical medicine was unhampered by multiple ancillary departments. There is a tendency to-day to desire quantity rather than quality; to report on 1,000 incompletely investigated cases in which calls have been made on all ancillary departments, rather than on one case after careful clinical examination over a period. Sir James Paget studied one case of osteitis deformans during the 20 years of its development and then described it. His description is as valuable to-day as when he contributed it. He had not the advantages, perhaps the disadvantages, of distraction of the ancillary services of radiology, biochemistry, etc., yet his description of his one case was so complete that little has since been added to our knowledge of that disease by many who have made great demands on these ancillary services in the investigation of many thousands of cases.

Radiology is now recognized as an essential aid to the study of anatomy, physiology, pathology, clinical medicine, surgery, and midwifery, and medical students must now be taught something of its possibilities throughout their university studies. This will result in a better and more complete knowledge of the possibilities of radiology, but this wider knowledge will mean that the radiologist, if he is to retain his high status and earn and keep the respect of his colleagues, must shoulder greater responsibilities and acquire an ever-increasing knowledge, for he can claim to be the general practitioner of the specialists. He should be in a position satisfactorily to render full co-operation to each.

Conclusion

It is fitting that in this City of Brotherly Love one should preach the gospel that radiology attains its highest perfection in the contribution to the relief of human suffering only when it is directed to spare the patient pain.

Wilhelm Konrad Roentgen (Brailsford, 1946b) was a man with sagacity and great ability. His observations were keen and extremely critical; he recorded them clearly, concisely, yet exhaustively, and with scrupulous care. His modesty, honesty, sincerity, and integrity to his science and his friends helped to secure his immortality. We follow in the footsteps of a great master, and it is fitting that I should end with the words of your great countryman:

> "Lives of great men all remind us
> We can make our lives sublime,
> And, departing, leave behind us
> Footprints in the sands of time."

VALUE OF SPHINCTER-PRESERVING OPERATIONS IN CANCER OF RECTUM

WITH SPECIAL REFERENCE TO RECONSTRUCTIVE ABDOMINO-PERINEAL EXCISION

BY

STANLEY O. AYLETT, M.B., B.S., B.Sc., F.R.C.S.

Surgeon, Metropolitan Hospital; Assistant Surgeon, Westminster Hospital (Gordon Hospital)

In 1908 Ernest Miles published the details of his operation for cancer of the rectum. Based as it was on close anatomical studies of the potential zones of spread of the disease, the abdomino-perineal excision came to be regarded as the standard operation for the treatment of cancer affecting any part of the bowel between the lower sigmoid and the anal canal. No limitation of the excision was regarded as permissible, no matter at what level the growth was sited, and it is only in recent years that doubt has been cast on the necessity for sacrificing the sphincter mechanism in those cases in which the neoplasm lies above this region.

Surgery in this country has remained very true to the teachings of the great master of proctology, and little has been published in the English journals in favour of sphincter-preserving operations. But in America much has been written and many divergent views have been expressed, and as great a surgeon as Rankin (1947) has said, in condemning all such operative procedures: "Sphincter-saving operations are little more than local excisions for cancer below the peritoneum. I had thought that the question of colostomy had been definitely settled 20 years ago, but apparently a new generation insists on a re-exploration of an already discredited field." On the other hand, Babcock (1932) and Bacon (1945) champion such operations in the majority of cases. Lynch (1945) goes so far as to say, in commenting upon recent pathological investigations: "It permits one to discard entirely such radical and unnecessary operations as that popularized by Miles."

Perhaps a far more acceptable opinion is that of Wangensteen (1947), who has recently said: "A tempered ambition to save the rectal sphincter, as well as to cure the cancer, is a praiseworthy objective in suitable cases of cancer of the upper rectal ampulla."

Support for this point of view is to be found in the follow-up figures of Babcock, in which, of over 80 patients considered suitable for a sphincter-preserving operation 50% survived disease-free for five or more years. Such figures can hold comparison with any series in which the wider abdomino-perineal operation has been performed for similarly sited growths.

Until the late 'thirties the idea of sphincter-preserving operations had lain largely dormant for three decades. Before Miles came to tower over his contemporaries, low excisions and anastomoses had been explored by the surgeons of the latter end of the last century and beginning of this. But enthusiasm for their employment was quieted by the logic of the great man. Maunsell (1939) had described a combined abdominal and perineal approach in which continuity was achieved after excision of the rectal growth. Balfour (1910) described a C. W. Mayo method of resection and anastomosis, again by a similar approach, but these very limited excisions were relegated to the past. Later, Lockhart-Mummery (

employed a method of restoration of continuity, but abandoned it as being too limited in its extent.

Lymphatic Spread in Rectal Cancer

What, then, has caused this controversy to break out once again? In 1935 Gabriel, Dukes, and Bussey published their paper on the lymphatic spread in cancer of the rectum. In 1938 Gilchrist and David published a similar work, and in 1940 Coller, Kay, and MacIntyre studied the regional metastasis in this disease.

From these and similar papers it appears that the downward and lateral spread of the disease had been overemphasized by Miles. In those cases in which the neoplasm is sited from 6 to 7 cm. or more above the anal orifice such spread occurs only in a late stage of the disease, when the haemorrhoidal lymphatics are already blocked by metastases and when the progress of the cancer has reached an advanced stage. It thus appears that, provided the upward zone of spread can be eradicated, and provided a suitable length of bowel is resected below the macroscopic margin of the tumour, a radical removal of the area of lymphatic spread can be performed with sphincter salvage and avoidance of a colostomy.

With regard to the submucous spread of the disease below the margin of the tumour, most pathological opinion is that it is very limited, and, indeed, such opinion was held by Miles (1936) as well. Black and Waugh (1948) suggest that it extends only to a maximum of 3 mm. from the tumour edge, but it is generally regarded as more extensive than this.

Nevertheless, the interpretation of these pathological findings must be correlated with the post-operative history of the patients. To his cost Wangensteen (1945) has found this out, and he has said: "Whereas Coller and his associates failed to find evidence of lateral lymphatic spread in lesions lying more than 3 cm. above the ano-rectal line, I am convinced from the experience with low-lying fixed lesions that an operation which does not excise the levatores ani in juxtaposition to the bowel invites recurrence."

Sphincter-preserving Operation

However, in selected cases a sphincter-preserving operation seems likely to carry as good a chance of recovery as the more extensive abdomino-perineal excision. Such an operation does not mean a local excision. The upward extent of removal must be as wide as in the operation of Miles. The clearance of pelvic peritoneum and underlying fascia, the removal of the tissues behind the rectum lying between it and the sacrum, and the excision of as much of the diaphragmatic portion of the levatores ani complex as is possible must all be included in the dissection.

It is for these reasons that I do not regard an anterior resection operation as radical enough in its extent. Babcock's operation fulfils all the anatomical requirements, but the interference with the sphincters at the time of operation is, I believe, something to be avoided if that can be achieved.

Removal by the combined abdominal and perineal routes, with primary suture of the bowel at the time of operation and leaving the sphincter mechanism untouched, is, I believe, the best approach. Reconstructive abdomino-perineal excision of the rectum undoubtedly leaves the patient with good faecal control.

In America this procedure was first suggested by Pratt (1938), and no doubt it has been tried by some proctologists in this country. It is not widely known, and is deserving of further record. In addition, certain modifications of the technique are worth emphasis.

Indications for the Operation: (1) The lower palpable margin of the neoplasm must be at least 7–8 cm. from the anal verge. (2) At operation there must be no evidence of extensive extramural spread. (3) If secondary deposits are present in the liver, or if there are advanced metastases in the aortic nodes, the sphincter-preserving operation is the one of choice. It offers the patient the greatest comfort in his remaining span of life.

Operative Technique

Ten days before the main operation transverse colostomy is desirable. In any case, if not performed before the main procedure it should be carried out at the end of the abdominal part of this operation. Faecal contamination of the perineal wound is thereby avoided should there be any breakdown in the perineal anastomosis. The remaining pre-operative preparation of the patient is the routine employed prior to Miles's operation.

Immediately before the operation an assistant passes a short sigmoidoscope and packs the rectum below the growth with cotton-wool soaked in 1 in 1,000 perchloride of mercury. This is an important detail. There is no doubt that during the manipulations of the rectum through the abdominal incision small portions of a friable growth may be broken off. When the rectum is subsequently excised through the perineum these small fragments may become implanted in the line of the anastomosis, giving rise to what is apparently a local recurrence. By packing the rectum with cotton-wool the small fragments of growth are held up and prevented from contaminating that area of the bowel through which the resection is going to be carried out.

The initial stages of the operation are those of the abdomino-perineal excision. A left paramedian incision is preferable in view of the fact that mobilization of the descending colon to a higher level is required. The pelvic peritoneum is incised in routine fashion and the rectum separated from the bladder, from the sacrum, and, by dividing the lateral ligaments, from the lateral pelvic walls.

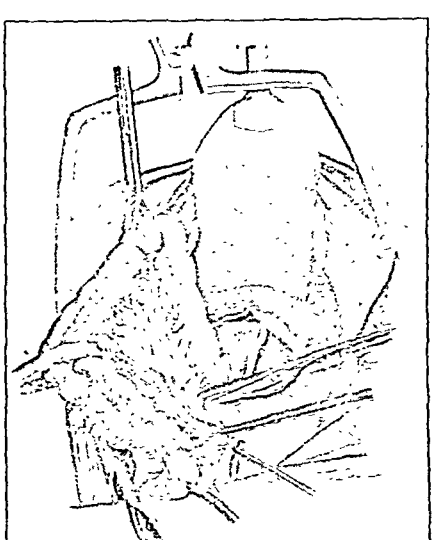

FIG. 1.—Composite plate showing the division of the mesocolon after mobilization of the bowel. The division is carried out as far as the mesocolic margin of the pelvic colon.

with ultra-violet light. Absence of effective sunlight may thus be more serious than dietary deficiency of the vitamin, and vitamin deprivation in such cases may be at least partly metabolic in origin.

Vitamin Deficiencies in the Sprue Syndrome

Vitamin deficiencies have been studied and a number of relevant investigations have been made in a series of cases of defective fat absorption in Birmingham (Cooke, Elkes, Frazer, Parkes, Peeney, Sammons, and Thomas, 1946). The results of these studies may be briefly reviewed.

Relatively Transient Nature of Deprivation.—In chronic cases of the sprue syndrome the fat-absorption defect persisted more or less unchanged over long periods. From time to time, however, the patient might complain of an exacerbation of certain symptoms—especially diarrhoea, with large, bulky, fermenting stools, sometimes associated with a sore ulcerated tongue and sore eyes. The haematological changes also showed exacerbations and remissions. This group of signs and symptoms seemed to come and go—as though superimposed on a more constant underlying defect.

Nature of Deficiencies.—The commonest deficiency signs and symptoms were those affecting the tongue and eyes. The majority of cases of sprue showed signs of glossitis. From time to time the tongue became enlarged, sore, and ulcerated, scarlet-red or magenta in colour, the conjunctival vessels might be injected, and the eyes sore, with excessive lacrimation and photophobia; cheilosis was also frequently seen. These changes were commonly associated with deprivation of riboflavin, nicotinic acid, and/or pyridoxin. Various haematological changes were also often observed. Macrocytosis was almost a constant feature of the sprue syndrome (Cooke, Frazer, Peeney, Sammons, and Thompson, 1948). These haematological changes were attributed to deficiency of folic acid and possibly other members of the vitamin-B complex. In occasional cases other vitamin deficiencies were observed.

Effects of Therapy.—In most cases of riboflavin, nicotinic acid, or pyridoxin deficiency in sprue parenteral administration of the appropriate vitamin fraction caused dramatic relief of the signs and symptoms of deprivation. Small doses were effective. In many cases very large doses of the vitamin were effective orally. It was not uncommon to find that the administration of one of the vitamin fractions by mouth might precipitate deficiency symptoms associated with some other fraction. Thus the administration of large doses of nicotinic acid might precipitate a classical ariboflavinosis. Increase of carbohydrate in the diet sometimes had a similar precipitating effect.

Relationship to Fat Absorption.—Relief of the signs and symptoms of vitamin-B deficiency was achieved in the sprue syndrome without alteration in the fat-absorption defect. Classical cases of ariboflavinosis have been observed in which fat absorption was normal. There seems no reason, therefore, to suppose that the vitamin-B deficiency is intimately related to the aetiology of the fat-absorption defect (Frazer, 1947).

Intestinal Flora.—A number of cases of the sprue syndrome have been intubated, using a technique devised by my colleagues Drs. J. M. French and M. D. Thompson, to minimize contamination. In hypochlorhydric cases thousands, and occasionally hundreds of thousands, of bacteria were observed per ml. of upper intestinal contents. In achlorhydric cases millions of viable organisms per ml. were demonstrated. The organisms were the usual inhabitants of the intestine, normally confined to the lower reaches. The type of predominating organism, the number of viable bacteria, and the level to which they reach will vary under differing environmental conditions.

Synthesis of Vitamins by Intestinal Bacteria.—Some attention has been paid to the question of bacterial synthesis of vitamins. In some cases of sprue the faeces contained more vitamins than the diet, in spite of a concomitant vitamin deficiency. Thus classical ariboflavinosis was observed in a patient passing three times more riboflavin in the faeces than was present in the diet—the amount in the diet being greater than normal requirements (Smart and Daley, 1946).

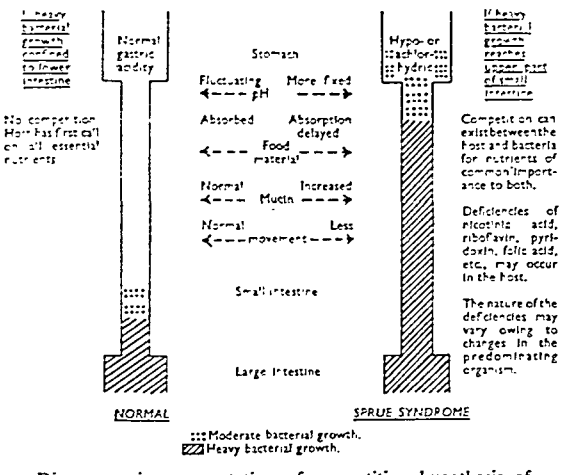
Effect of Antibacterial Agents.—Antibacterial agents may stop severe diarrhoea at least-temporarily (Keele, 1949). The effect of antibacterial agents on vitamin deficiencies is unknown. An interesting observation was made using sulphasuxidine. Usually less than 10% of this drug was absorbed and the sulphathiazole level in the blood was negligible, <1-2 mg. per 100 ml. of blood. In two cases of sprue the administration of sulphasuxidine by mouth resulted in blood levels of sulphathiazole of 10.6 and 13.8 mg. per 100 ml.

Discussion

Dietary inadequacy is certainly not a common cause of vitamin deficiency in the sprue syndrome. It may account for the occasional case of vitamin-E deficiency, especially since oxidative rancidity of fats may be one of the precipitating causes in tropical sprue. It does not account for any of the common vitamin-B deficiencies. There is no evidence of any metabolic fault of vitamin-B utilization in the sprue syndrome. Parenteral administration of the appropriate vitamin fraction secures immediate relief in the vast majority of cases.

An absorptive defect due to interference from unabsorbed materials may account for the occasional vitamin-A or vitamin-D deficiency; the latter is further complicated by changes in calcium absorption. Again, the common vitamin-B deficiencies are not due to a faulty absorptive mechanism, since large doses are often effective by mouth and the normal dietary intake is adequate in remission. There is no evidence of faulty digestion of vitamin precursors. It would seem, therefore, that the common vitamin-B deficiencies observed in the sprue syndrome do not fit into any of the known deprivation groups.

The selective nature of the vitamin-B deficiencies—nicotinic acid, riboflavin, pyridoxin, and folic acid—in sprue is very striking. The deficient vitamins are all essential growth factors for bacteria—particularly those bacteria which are known to be present in the upper part of the small intestine in sprue. Large numbers of these bacteria can be demonstrated in the upper small intestine by intubation, and their presence is also indicated by the results of sulphasuxidine administration: clearly, in the sprue syndrome the bacterial decomposition of sulphasuxidine is occurring within the absorbing area. It is well known that bacteria will first take up preformed growth factors and then synthesize more of these vitamins if necessary. In sprue the bacteria may synthesize further vitamins; it is likely that they will take up as much preformed vitamin as possible before doing so. It is therefore suggested that in the sprue syndrome intestinal bacteria invade the upper small intestine from time to time in large numbers. This bacterial invasion may give rise to large, bulky, fermenting stools. It also results in competition between the bacteria and the host for common essential nutrients. In many cases the bacteria are the most successful competitors and the host consequently shows signs of deprivation.



This competition hypothesis would account for the exacerbation of vitamin deficiencies and diarrhoea associated with heavy growth and high-level invasion of intestinal bacteria. This bacterial invasion may be related to fixation of *p*H as a result of achlorhydria, and possibly the presence of suitable food materials due to delayed absorption. The competition hypothesis would also account for the peculiar selective deficiencies observed in the sprue syndrome. It might also explain the administration of one vitamin precipitating the deficiency of another, since bacterial growth would be stimulated by the one and would increase the demand for the other. In oral administration of the vitamins, sufficient vitamin must be given to provide both

for the bacteria and for the host. Hence the large dosage required in oral therapy. It is also recognized that modifications of the dietary regime which are known to alter intestinal flora affect the sprue syndrome.

The part played by intestinal bacteria in vitamin synthesis in normal human subjects is obscure. It has been suggested that the modification of intestinal flora by sulphonamides or other antibacterial agents might result in faulty synthesis of vitamins and consequent vitamin deprivation. This conception of vitamin deprivation is mainly based upon experimental studies in animals and especially upon the phenomenon of refection (Kon, Kon, and Mattick, 1938). Rats and rabbits may not develop certain vitamin deficiencies when placed upon an appropriate vitamin-deficient diet. This can be shown to be at least partly due to the synthesis of B vitamins by intestinal bacteria.

The inclusion of certain types of starch in the diet and initial coprophagy are probably important factors in the establishment of refection. In some animals on a deficient diet prevention of coprophagy results in the development of vitamin deficiencies in spite of continued intestinal synthesis of the vitamins. The vitamins synthesized by intestinal bacteria can be utilized by the body only if they are released from the bacteria and absorbed from the intestinal tract. The formation of B vitamins in the large intestine in man and their continued inclusion in viable bacteria greatly limit their availablity. The conditions within the intestine in the refected rat may resemble to some extent those prevailing in the human intestine in the sprue syndrome; the possible importance of starch fermentation in both cases is of special interest. It seems clear, however, that the synthesized vitamins are much more readily available to the rat than to the human subject.

Vitamin synthesis by intestinal bacteria in the normal human subject is probably limited in extent and mainly confined to the large intestine—it is therefore unlikely to play a major part in the vitamin economy. In the sprue syndrome, synthesis may be greatly increased and the site of formation may now include normal absorbing areas. In spite of this, vitamin-B deficiencies now occur, which would suggest that the synthesized vitamins are not available for absorption, possibly owing to their retention within viable bacteria. The competition hypothesis is put forward here in its simplest possible form, but it is clear that many complexities may develop in individual cases. Some aspects of refection in rats might be usefully examined in relation to the changes in intestinal flora which can be observed in the sprue syndrome.

Diagrammatic representation of competition hypothesis of vitamin deficiencies in the sprue syndrome.

This paper is especially concerned with vitamin deficiencies in the sprue syndrome. Special consideration must be given, however, to the possible importance of intestinal bacterial competition in other conditions. A similar competition situation must arise in pernicious anaemia, in which vitamin-B deficiencies are well recognized—much of the haematological picture being ascribed to them. In this condition there is, however, apparently normal fat and glucose absorption, a normal radiographic pattern, and an absence of fermentative changes. These points serve to emphasize the lack of intimate relationship between the absorptive defects in the sprue syndrome and the changes in intestinal flora and consequent vitamin deficiencies. It is possible that the absence of absorptive defects in pernicious anaemia and consequent environmental differences may result in qualitative and quantitative modifications of the intestinal flora, with resultant differences in metabolic demands. The possibility of intestinal bacterial competition along the lines indicated in this paper should be investigated not only in the sprue syndrome but in various other conditions which are thought to be closely associated, such as pernicious anaemia, pellagra, and nutritional megalocytic anaemia (Manson-Bahr, 1940, 1941). The metabolic demands of a varying but essentially non-pathogenic flora may be the key to the problem of the multiple but selective vitamin deficiencies so commonly observed in these conditions.

Original observations reported in this paper have been made as part of a team-work study on fat absorption and the sprue syndrome which is being carried out with my colleagues, W. T. Cooke, J. M. French, T. L. Hardy, A. L. Peeney, H. G. Sammons, G. Thomas, and M. D. Thompson, at the Medical School and Hospitals Centre, Birmingham. We are indebted to the Medical Research Council and the Sir Halley Stewart Trust for financial assistance.

The Ministry of Health states that more blood was given for hospitals in England and Wales in the second quarter of this year than in any comparable period since the war. New donors in the quarter numbered 36,847—the biggest response since the war—bringing the total strength of donor panels to 382,382. Hospitals are now using over 40 times as much blood as before the war, and the demand is still rising. To provide for these future needs it is estimated that over 190,000 more donors are wanted.

TUBERCULOSIS OF THE BREAST

BY

RONALD W. RAVEN, O.B.E., F.R.C.S.

Surgeon to Westminster Hospital (Gordon Hospital) and to the Royal Cancer Hospital

It appears from a survey of the literature that little attention has been paid during recent years to this subject in English writings. The opportunity is taken, therefore, in presenting this case record, to review the general features of the disease and stress its importance in the differential diagnosis of lesions of the breast. It is important to appreciate the close similarity between certain forms of tuberculosis and carcinoma of the breast, and differentiation is often rendered difficult; many of the cases of primary tuberculosis reported in the literature were diagnosed incorrectly as carcinoma, and it was only after operation and pathological study of the tissues that the true situation was disclosed.

Case Report

A woman aged 43 developed a swelling in the left breast in May, 1947, following a blow through a fall one month previously. The swelling was regarded as mastitis of the upper and inner quadrant. In September the left breast became red and tense, and an abscess was incised and drained. Pathological investigation of the tissues showed chronic inflammation with no giant-cell systems or tubercle bacilli. After the operation a small sinus persisted, with slight discharge. On January 6, 1949, a small red swelling developed in the upper and outer quadrant of the left breast, and this became cystic and tender. Aspiration yielded 1.5 ml. of purulent fluid which showed tubercle bacilli on microscopy.

She had had amenorrhoea between May, 1947, and February, 1948—before this the cycle was 28 days and the duration five days—and again since April, 1948. She had never been pregnant. Her general health was good; no cough or pain in the chest. When 4 years old she had had tuberculous peritonitis, with operative treatment. In December, 1914, an operation had been performed on the left cervical lymph nodes. One brother had had tuberculous cervical lymphadenitis as a child.

On examination the patient looked healthy. Her neck showed scarring on the left side; no enlarged lymph nodes. The heart and lungs showed no gross abnormality. Scars of previous operations were seen in the right hypochondrium, but no other abdominal abnormality was found. The right breast was normal. In the lower half of the left breast there was a discharging sinus with an associated abscess; a red fluctuating tender swelling was seen in the upper and outer quadrant (see Fig.). No marked induration of the breast tissue was present. The lymph nodes in the axillae were not enlarged. *X*-ray examination of the chest revealed no abnormality.

Photograph of the affected breast, showing the tuberculous lesion in the upper and outer quadrant. There is an area of puckering in the lower and inner quadrant.

Operation. — Local mastectomy and excision of the fourth costo-chondral junction, left side. It was noted that the sinus in the lower part of the breast was connected with a caseous process in the fourth costo-chondral junction, left. The wound healed by first intention.

Study of Specimen.—In the left breast there was an abscess situated above and external to the nipple. The skin over the abscess was bluish in colour. On opening into the abscess cavity it was seen to contain yellow caseous material. In the lower and inner quadrant of the breast there was an area of puckered scar tissue. Sections through the breast beneath this scar tissue showed a sinus which could be traced through the substance of the breast to its deepest part. This sinus contained caseous material and was presumably connected with the rib which was resected. A piece of resected rib was partly replaced at the costo-chondral end by an irregular mass of granulation tissue. On histological examination both the wall of the abscess cavity and the sinus showed tubercles composed of endothelial cells surrounding areas of caseation. There was also a small round-cell infiltration. Breast tuberculosis was diagnosed.

General Features of the Disease

The condition was described in the first instance by Sir Astley Cooper, who wrote in 1829: "In young women, who have enlargement of the cervical absorbent glands, I have sometimes, though rarely, seen tumours of a scrofulous nature form in their bosoms, confined in most cases to a single tumour in one breast; but in one case, two existed in one breast, and one in the other. They are entirely unattended with pain, are distinctly circumscribed, are very smooth on their surfaces, and scarcely tender to pressure. They are very indolent, and vary with the state of the constitution, diminishing as it improves, and increasing as the general health is deteriorating." He pointed out that the condition does not degenerate into malignancy, and surgical treatment is contraindicated. His concluding remarks were: "It will be admitted by every one who deserves the title of a surgeon, that we possess no specific remedy for this disease, but that we are required to assist the digestive powers, make better blood, and convey it to the system by an increased vigour of the constitution." Since this publication over 500 cases have been reported in the literature.

The incidence has been computed at various figures: thus, Nicolson and Gillespie (1941) consider the incidence of tuberculosis compared with all breast lesions to be 0.54%; McGehee and Schmeisser (1935) give a figure of 1.87%. On this basis it is not a common condition, but it is possible that a number of cases are overlooked, the rarity being apparent rather than real.

There are two main varieties—namely, primary tuberculosis, in which there is no evidence of a tuberculous lesion elsewhere in the body, and secondary tuberculosis, in which there is evidence of a tuberculous lesion elsewhere, such as in the lungs, pleura, lymph nodes, or bone. The various lesions can be grouped under three headings as follows:

Nodular Lesion.—A circumscribed lump of variable size forms in the breast, slow caseation occurs with softening of the tissues, and eventually an abscess forms which may produce a sinus in the overlying skin.

Sclerosing Lesion.—A circumscribed lump develops which is hard in consistency owing to excessive fibrous-tissue formation. This variety is seen in older patients.

Atypical Lesions.—A tuberculous ulcer develops in the skin near the nipple and nodules are formed in the breast tissue later; a subcutaneous lesion develops which resembles a furuncle; or vesiculated pimples form with indurated bases.

Mode of Entry of Tubercle Bacillus

Considerable discussion has been aroused regarding the possible routes of entry. The organisms may gain an entrance through the ducts of the nipple or through an abrasion in the skin, but these must be remote possibilities, although several cases have been reported. Thus, Morgen (1931) quotes Ingier, who described a case in which the inflammatory process was confined to the walls of the excretory ducts and the periacinous tissue, the interacinous tissue

being only slightly involved. Morgen also quotes Ely, who mentions a woman who covered her breast with a piece of linen contaminated with tuberculous sputum and soon after developed tuberculosis in this breast.

Haematogenous infection may occur, although Nagashima (1925) investigated 34 patients who died of miliary tuberculosis, studying the breast tissue microscopically, by smears, and guinea-pig inoculations, but was unable to demonstrate any involvement. The case recorded above is instructive in that multiple tuberculous lesions developed at long intervals in widely separated parts of the body, and it is assumed the tubercle bacilli were transported by the blood stream.

Many authors have stressed the importance of infection by the lymphatic system; the primary lesion being cervical, axillary, or mediastinal tuberculous adenitis, and the breast being affected by retrograde infection. Morgen quotes Halsted and Le Court, who state that there is tuberculous axillary adenitis on the same side as the affected breast in 75% of cases, and Berchtold, who found the primary disease in the axillary lymph nodes and the secondary in the breast in 8 out of 37 cases reported. He also calls attention to a case described by Johannet in which at necropsy subpleural tuberculosis was demonstrated, extending to the axillary lymph nodes and eventually to the breast.

Finally, the breast may be involved from underlying tuberculosis of the sternum, costo-chondral junction, or rib. In this case the lower of the two lesions extended directly down to a diseased costo-chondral junction.

Symptomatology and Differential Diagnosis

The disease occurs between the ages of 20 and 50, when the breasts are most active. The majority of patients are apparently in good health; some may give a past history of tuberculosis, as did my patient, who had had tuberculous peritonitis and cervical adenitis. The most frequent presenting symptom is a lump in the breast, which is often painless and discrete.

When caseation is present the border of the lump is well defined. The overlying skin shows certain changes; thus there is often fixation and dimpling with retraction of the nipple, or it is stretched and red, sinus formation developing later. Retraction of the nipple may be the first sign of the disease. An abscess is present sometimes, and Morgen states that a fistula is seen in 50% of cases. Tubercle bacilli may be demonstrated in the discharge. Other lesions may be present in the breast, including fibro-adenoma or carcinoma.

Enlargement of the axillary lymph nodes is often present, and this may precede the development of the disease in the breast. A radiological examination of the chest should be made in every case; Grausman and Goldman (1945) state that pulmonary tuberculosis is present in 12 to 16% of cases. The disease is usually unilateral, but cases with both breasts involved have been reported.

The following diseases must be considered in the differential diagnosis.

Carcinoma.—Many of the reported cases of tuberculosis of the breast were misdiagnosed as carcinoma, and differentiation may be difficult, especially in the sclerosing types. The degree of hardness is greater in carcinoma and the axillary lymph nodes may also be hard. The deformity of the nipple may be greater in carcinoma. Tuberculosis tends to occur in younger age groups than carcinoma, and there may be a purulent discharge from the nipple. When a sinus is present it may be possible to isolate the tubercle bacillus; in all doubtful cases a biopsy and histological examination must be performed.

Benign Fibro-epithelial Tumours.—Differentiation is not difficult usually in these cases. The tumours are circumscribed and encapsulated and mobile in the breast tissue. There is no involvement of the overlying skin nor any change in the nipple. The axillary lymph nodes are not enlarged.

Cystic Hyperplasia.—In this condition both breasts are often involved and the swellings produced are larger. The cysts are palpable, causing an uneven surface in the swelling. There are no changes in the overlying skin. The axillary lymph nodes are not enlarged.

Acute Mastitis.—Differentiation is not difficult in this instance. There are fever and other general symptoms of an acute infection, and locally the cellulitis, with or without abscess formation, is typical of the condition.

Actinomycosis.—When a discharging sinus is present, together with an indurated swelling in the breast, actinomycosis must be considered, although this is an uncommon lesion. The typical sulphur granules may be present in the discharge and the fungus isolated.

Gumma.—This is an uncommon lesion in the breast; degeneration may occur with sinus formation in the skin. A Wassermann test and biopsy will help in the diagnosis.

Traumatic Fat Necrosis.—There may be a history of an injury to the breast, causing a localized hard swelling without any inflammatory signs. Biopsy and microscopical examination may be required to determine the diagnosis.

Association of Tuberculosis with Carcinoma of Breast

The presence of tuberculosis and carcinoma in the same breast has been noted on a number of occasions. Thus, Grausman and Goldman (1945) collected 26 cases from the literature and added two cases of their own. It is obviously important to remember this possibility, as an associated carcinoma may be overlooked, with serious consequences for the patient. Morgen discussed the interpretation of the relationship of these conditions. The two conditions may occur independently, either simultaneously or consecutively. The tuberculosis may be engrafted on the malignant condition as a result of the greater susceptibility of breaking-down tissue to infection. It is possible that the carcinoma is the result of the chronic irritation of the tuberculous inflammatory process.

In a number of these cases it was thought that the carcinoma was of longer duration in the breast and of a fibrous type; the tuberculous lesions showed no calcification, so it is possible that tuberculous infection occurred in tissues of decreased resistance or increased susceptibility. In some cases of carcinoma of the breast it was found at operation that there was tuberculous adenitis in the axillary lymph nodes. The breast is not the only site where these conditions coexist, for carcinoma has been found in chronic tuberculous cavities in the lungs.

Treatment

The maintenance of the patient's general health is important, as in all cases of tuberculosis. When the disease is localized to the breast and there is no evidence of involvement of the axillary lymph nodes, local mastectomy should be performed. If there is enlargement of the axillary lymph nodes mastectomy is combined with excision of these lymph nodes, and a careful dissection of the axilla is necessary. In order to carry this out the tendons of the pectoralis major and pectoralis minor muscles should be divided to open up the axilla; at the end of the dissection the tendon of the former muscle is sutured. If the underlying costo-chondral junction or rib is involved, this must be excised. When tuberculosis and carcinoma coexist a radical mastectomy is performed with or without high-voltage *x*-irradiation, according to the type of carcinoma which is present. Now that streptomycin is available in greater quantities its action in cases of tuberculous mastitis may be beneficial,

and before resorting to surgery in the future, the effects of this drug should be tried.

Summary

A case record is presented of tuberculosis of the breast and underlying costo-chondral junction. The patient gave a history of old tuberculous peritonitis and tuberculous cervical adenitis. Tubercle bacilli were isolated from the discharging sinus. The general features of the disease, the symptomatology, and the differential diagnosis are described, and special emphasis is laid on the importance of differentiating carcinoma. Attention is called to the association of tuberculosis and carcinoma in the same breast. The treatment is described for various types of case.

I wish to thank Dr. J. H. O. Earle for studying the pathology of the specimen, and Dr. Peter Hansell for the photograph.

SOLITARY CEREBRAL METASTASES FROM BRONCHIAL CARCINOMATA

THEIR INCIDENCE AND A CASE OF SUCCESSFUL REMOVAL

BY

GEOFFREY FLAVELL, F.R.C.S., M.R.C.P.

(From the Department of Thoracic Surgery, London Hospital)

The extirpation of metastases is not generally regarded as a rewarding surgical practice, and although many an abdominal surgeon must have been tempted to resect an apparently single deposit in the liver, and many a thoracic one must at some time or other have mistaken a secondary tumour in the lung for a primary lesion, few records of their experiences exist, and fewer still of the planned removal of both primary and secondary growths.

One is apt to assume that the appearance of a metastasis inevitably implies the existence of others and the certainty of death, and examples in the literature to support a contrary hope are rare. In 1946 Alexander and Haight were, however, able to collect the histories of 24 patients who had undergone pulmonary resections for solitary metastases in the lung after previous excisions of the primary growths, 15 of which were carcinomata and eight sarcomata. Of the 24, one died, 11 had recurrences, but 12 remained free; and among the latter eight survived their resections by more than a year. One patient (who lived 12 years) had originally been operated upon by Barney (1944a, 1944b) for a renal adenocarcinoma, the lung metastasis having been seen a year before his nephrectomy and removed a year later, so that its malignancy must have been low. Six other of the primary lesions were also renal-cell carcinomata, and it is of interest that both Bumpus (1928) and Beer (1937) have reported spontaneous regression of such metastases.

Albright in 1944, Friedman in 1943, and Turner and German in 1941 have described in all four instances of successful extirpation of characteristically slow-growing skull metastases from thyroid carcinomata; and Cattell (1940) reports a patient well one year after the removal of a solitary secondary in the liver at the abdominal stage of an abdomino-perineal resection of a rectal carcinoma. He argues, "The patient is better off with a large focus of malignancy removed, and there is at least some clinical evidence that there may be retardation of the malignant process."

The only successful removal on record (apart from the one reported below) of both primary and cerebral secondary growths was carried out by Thurel in 1942, when he excised a deposit from the right frontal lobe of a patient who had had a Halsted operation for carcinoma of the breast exactly a year previously. She remained symptomless two years later (Alajouanine, Thurel, and Longuet, 1944).

The incidence of cerebral metastasis in carcinoma of the lung was estimated by Ochsner and de Bakey, reviewing 3,047 patients, to be 16.5%. Other authorities put the figure even higher—Graham and Wagner at 24% and Olsen at 36%. In 448 proved pulmonary cancers Tinney and Moersch (1944) found that 19 (4%) presented with central nervous symptoms, and in these people the average duration of life from the onset of their symptoms was six months.

In the necropsy records of the London Hospital from 1909 to 1949 I have been able to find 85 examples of cerebral metastases accompanying a primary bronchial carcinoma. Of these, 26 were single in the brain or cerebellum—a percentage of 31 in a group of whom many died in the extremity of their disease, with numerous secondary deposits elsewhere in their bodies. Furthermore, eight (9.4%) were completely solitary in the body (if removable hilar glands alone be ignored); the cerebral lesion was a lonely satellite of the pulmonary primary growth—one, indeed, occurred two years after a successful pneumonectomy.

Case Report

In June, 1947, a man aged 34, in a responsible clerical position, was found on mass radiography to have a circumscribed shadow at the hilum of his left lung. He had had no symptoms of any sort, but one day in October he developed a headache, accompanied by noises and followed an hour later by an epileptiform fit in which he lost consciousness for 10 minutes and was incontinent of urine. This was not repeated, but frontal and vertical headaches persisted and were later associated with occasional diplopia, flashes of light, and other visual disturbances. He was admitted to the London Hospital on November 22, 1947, and except for early papilloedema, very slight left lower facial weakness, and equally slight bilateral hypotonia (a little more pronounced upon the left side), he had no abnormal physical signs either of his chest or of his nervous system. Lumbar puncture revealed a pressure of 210 mm., and the protein content of the cerebrospinal fluid was raised to 120 mg. per 100 ml. Although bronchoscopy was negative, there seemed to be little doubt that a primary carcinoma of the left lung was accompanied by a cerebral metastasis. Since the necropsy findings on similar patients, as already mentioned, gave some encouragement, a deliberate plan was then made to attack the secondary deposit, and, if it proved operable and was single, subsequently to remove the lung with its primary growth.

Because the symptoms and signs of raised intracranial pressure became severe, a palliative right subtemporal decompression was performed on December 18. This proved effective, and on January 8, 1948, ventriculography showed displacement of the system to the left, with no filling of the right ventricle, indicating a large right-sided lesion. Consequently a right fronto-lateral exploratory craniotomy was carried out by Mr. D. W. C. Northfield; this revealed a highly vascular lobulated mass about 7 by 4 cm., occupying a superficial position in the right temporal lobe, but not transgressing the Sylvian fissure. It was secondarily adherent to the dura mater over some 2 cm.^{2} The whole tumour, with a narrow margin of apparently healthy brain tissue, was removed with the overlying adherent dura. Histological section proved it to be a secondary carcinoma, but gave little indication of its origin.

The patient made a good recovery, and eight weeks later was readmitted, this time to the thoracic surgery department.

Radiographs showed that the chest opacity had very considerably increased in the past three months, but bronchoscopy remained negative. On March 11 a left pneumonectomy was carried out by Mr. Vernon Thompson. The growth, which was in the hilar region, was massive, but no enlarged mediastinal glands were found, and there was no growth in several hilar glands later sectioned. The tumour was a squamous-celled carcinoma. Convalescence was again uneventful, but in view of the dural adhesions the patient was referred to Dr. Frank Ellis for deep *x*-irradiation of the region of the cranial defect. No radiation was given to the chest.

At the time of writing, 18 months after the removal of his lung, the patient is well, works a full day in his exacting employment, and has no sign of recurrence or of any further metastasis.

I am indebted to Mr. D. W. C. Northfield and to Mr. Vernon Thompson for permission to publish this case history; and to Professor Dorothy Russell and Dr. W. W. Woods for their kind assistance.

HUMAN INFESTATION WITH TRICHOSTRONGYLUS IN SOUTH PERSIA

BY

IAN S. STEWART, M.B., Ch.B.
Pathologist, Anglo-Iranian Oil Co., Ltd.

An investigation of the worm infestation of the labourers employed by the Anglo-Iranian Oil Company at their refinery at Abadan was undertaken in January, 1947. These men numbered 30,000, and from the routine investigations made in the company's pathological laboratories it was believed that about one-quarter of them harboured hookworm and about one-sixth of them *Ascaris*. *Trichuris*, *Enterobius*, and *Hymenolepis* were known to be much less frequent.

Abadan Island is mainly arid desert, except for a belt of date palms at its margin and in the residential areas close to the refinery, where abundant irrigation by pumped river water is available. For most of the year the climate is extremely hot and dry, the rainfall occurring only in the cool winter months. The refinery area is furnished with metalled roads, and the labourers wear shoes except when in their own homes. The conditions therefore are the very reverse of those in which ankylostomiasis would be frequent.

"Ground itch" around the ankles is not seen, grave anaemia is infrequent, and attempts to dislodge the worms by means of such drugs as carbon tetrachloride and tetrachlorethylene had been consistently unsuccessful. One notable case was that of a British medical officer who had passed ova for five years in spite of the use of all known treatments and who had remained in excellent health except when enduring the discomforts of purgation.

Present Investigation

Technique of Laboratory Investigation.—(1) A fragment of freshly passed faeces was emulsified in saline on a slide, and a cover-slip applied. (2) A considerable quantity of faeces was intimately mixed with saturated sodium chloride solution in a test-tube, filled to the brim, and a slide placed in contact with the upper surface of the fluid. After 30 minutes the slide was removed and a cover-slip placed on the adherent fluid.

Altogether 1,000 specimens were examined. During the examination it became evident that two distinct eggs were being diagnosed as those of hookworm. In the accompanying Table these are quoted together as "hookworm."

Parasite	In Direct Film	In Flotation	In Direct Film Only	Total Reported
"Hookworm"	278	675	20	695
Ascaris lumbricoides ..	162	211	55	266
Trichuris trichiura ..	25	74	13	87
Hymenolepis nana	8	17	3	20
Double infestation ..	—	—	—	229
Treble infestation	—	—	—	21
No infestation	—	—	—	173

Enterobius vermicularis was not seen in this series, and is distinctly rare. The ova were reported only [illegible] times in 19,000 routine specimens in the year 1948, but no special methods such as anal scraping were employed. Similarly *Taenia saginata* was not encountered, but it is fairly frequent, ova or segments having been found 144 times in the same series of 19,000. *Taenia solium* is unknown, but is not to be expected among a people whose religion forbids the eating of pork.

The differences noted between these two "hookworm" ova before the identity of both was established were as follows: One was the characteristic *Ancylostoma* egg with rounded ends, one, two, or four blastomeres, and an opalescent appearance. The other was somewhat larger, always showed advanced segmentation, and had one end rounded and the other slightly pointed. It lacked the opalescent appearance of true hookworm and was much more clearly visible under the low-power objective of the microscope.

Once the distinction was established, the number of each appearing in the second 500 specimens was recorded and found to be 16 of the true hookworm and 324 of the false. This agrees fairly well with the figures recorded for the year 1948, when all the technicians were familiar with the two types: 67 cases of true hookworm were reported and 1,671 of its imitator.

Craig and Faust (1945) describe *Trichostrongylus* as a very frequent parasite of sheep and goats. Thirty samples of faeces were therefore collected from sheep intestines obtained from the local slaughterhouse and ova identical with those found in human faeces were observed in all of them. In addition adult worms were discovered in five of the sheep.

The adult worms have not been found in man. The population is overwhelmingly Moslem and the strongest objection is made to necropsies. Consequently only an occasional medico-legal necropsy is done, and, although a search is made for *Trichostrongylus* on each occasion, this has so far yielded no results and the species remains unidentified. Five patients were admitted to hospital and treated with a succession of anthelmintic drugs, but no worms were found in the stools and the men all continued to pass ova. This is in accordance with Maplestone's (1941) statement that no effective means of eradicating the worms is known.

Although final and complete proof that this second parasite was *Trichostrongylus* had not been obtained, as the adult worms had not been isolated, the parasite was assumed to be of this genus for the following reasons: (1) The climate is not one in which the life cycle of *Ancylostoma* could favourably be completed; (2) the wearing of shoes

and boots renders invasion of the skin by *Ancylostoma* larvae improbable; (3) "ground itch," associated with skin invasion by *Ancylostoma* larvae, is not seen; (4) mass infestation by *Ancylostoma* yields a considerable proportion of cases of grave anaemia; (5) anthelmintic drugs have been found to be almost useless in eradicating the worms; (6) the ova agree in every detail with the published description of *Trichostrongylus*; and (7) ova identical with those found in man were observed in a series of sheep examined.

Details of these findings and conclusions were therefore circulated among the company's medical officers, recommending that anthelmintic treatment should not be employed for the presumed *Trichostrongylus* infestations but only for the other helminths reported.

Symptomatology of Trichc trongylus Infestation

Maplestone (1941) considers that no significant symptoms occur in man. Faust (1939) considers that a heavy infestation may produce a severe secondary anaemia, but in the series encountered here the ova have always been scanty. In Abadan, in 1946, of 150 labourers who had been diagnosed as suffering from "hookworm disease" only six cases had a haemoglobin of less than 10 g. % and only one of these had a reading of less than 7 g. %. It seems probable that these six men were the genuine cases of ankylostomiasis in the series.

Forty healthy and symptomless school-children aged between 10 and 12 years were sent for investigation by the schools medical officer. Thirty-one were passing *Trichostrongylus* ova, and this provides additional evidence of the trivial nature of the infestation.

Mode of Transmission.—Man contracts the infestation by swallowing the larvae, and Watson (1946) quotes a number of isolated cases in Europe and the United States which were traced to sheep or goats. Although these animals are numerous on Abadan Island, few of the labourers are in close contact with them. Presumably the parasite is now being passed from man to man.

Diagnosis.—Watson in his paper deals at length with the points differentiating *Ancylostoma* ova from *Trichostrongylus.* He states that segmentation in tropical heat is so rapid that any delay in examination renders this distinction useless. The 1,000 cases examined in Abadan all passed stools on paper in the latrines adjoining the laboratory and handed the specimen to a technician immediately. Consequently the degree of segmentation has been of considerable diagnostic value.

Summary

An investigation of the relative frequency of human infestation with *trichostrongylus* in South Persia is described: 70% of the inhabitants carry the harmless sheep parasite *Trichostrongylus* and 25% the common *Ascaris.* Other helminthic parasites are rare.

A long-standing confusion of *Trichostrongylus* ova with *Ancylostoma* ova had occurred, with the provision of much ineffective treatment and waste of time. Part of a large labour force had been consuming unsuitable drugs intermittently, in some cases for a considerable period, and had thus been impeding the work of a very busy out-patient department.

I am indebted to Mr. A. C. Turner, Chief Medical Officer in Iran and Iraq, of the Anglo-Iranian Oil Company, for permission to publish this investigation, and to Professor J. J. C. Buckley, of the University of London, for criticism and advice.

A CASE OF PULMONARY STRONGYLOIDIASIS

BY

FINTAN L. CORRIGAN, L.R.C.P.I.
Acting Medical Superintendent, West Regional Sanatorium, Castlerea

The following case presents two interesting features of *Strongyloides stercoralis* infestation with pulmonary manifestations. It is interesting as a case treated for 12 months for pulmonary tuberculosis.

Case Report

An Army sergeant aged 51, with 32 years' service in India, Gibraltar, Hong Kong, Singapore, Shanghai, Egypt, and Palestine, was admitted to the Military Unit, Harefield County Hospital, in March, 1947. He had had an acute illness in April, 1946, with pain in the right side of the chest, and was admitted to hospital, where he was found to have a right-sided pleural effusion. He was given 30 g. of sulphathiazole, an underlying lobar pneumonia being presumed, but the pyrexia continued. Aspiration of the chest produced 1 pint (570 ml.) of greenish fluid, which contained 8,730 white cells per c.mm. These were predominantly lymphocytes and the fluid was sterile. No tubercle bacilli grew on culture. He was treated by repeated aspirations and air replacement of the effusion, the fluid becoming haemorrhagic and later pocketing at various levels. In May, 1946, he was found to have an opacity in the left mid-zone and a slight tender enlargement of the liver. After that he had further aspiration of fluid and prolonged rest in bed. The condition gradually improved. Sputum tests were persistently negative for tubercle bacilli, as was repeated fluid culture. In July he was transferred to another hospital; so before admission to Harefield he had spent periods in three hospitals, amounting to nine months.

On admission his general condition was good. He was afebrile. He had a slight cough, with a small quantity of frothy sputum but no pain (previously he had stabbing pain in the right side of his chest). There were no night sweats and no haemoptysis. Occasional attacks of asthma were relieved by ephedrine. He was gaining weight (he had lost 3 st. (19 kg.) during his illness). There was no diarrhoea and no history of pruritus or anal bleeding.

On examination pronounced wasting of the right side of the chest was seen with diminished movement and dullness over the right base and impairment of breath sounds in this area. Harsh rhonchi were heard over both lungs. There was nothing else of note apart from bilateral Dupuytren's contractures. A blood count showed: haemoglobin, 110%; red cells, 5,950,000; white cells, 9,800 (polymorphs 43%, eosinophils 30%, lymphocytes 21%, monocytes 6%). The B.S.R. was 10 mm. in one hour (Westergren).

On culture the sputum was repeatedly negative for tubercle bacilli.

A radiograph showed the heart and trachea to be displaced to the right. The appearance of the right lung suggested pleural effusion or residual pleural thickening, together with infiltration of the apex. The left lung seemed to be clear, the previous lesion having apparently resolved.

In view of the eosinophilia (30%) a specimen of stools was sent to the laboratory, which reported numerous *Strongyloides stercoralis* larvae in the specimen.

The patient continued to have frequent attacks of asthma, often twice daily, which were relieved by ½ gr. (32 mg.) of ephedrine hydrochloride.

Attempts were made to clear the infestation by using gentian violet capsules (1½-hour coating) 1 g. three times daily half an hour before meals until 50 g. were given. In view of the pulmonary symptoms, intravenous gentian violet (15 ml. of a 0.5% solution) was injected on alternate days for a month. Both these courses were carried out simultaneously. They

were without effect on the clinical condition, and the larvae persisted in the stools. A second attempt was made with hexylresorcinol. The patient, who had been given a saline purgative the previous day, received 9 g. of the drug at 6 a.m. No food was given for five hours, and a saline purgative was administered 24 hours after the dose. Following this treatment the majority of larvae in the stools were dead and there was considerable difficulty in finding any living ones. During this period, which lasted ten days, the patient was free from attacks of asthma. A specimen of stools ten days after the dose had been given contained numerous living larvae and the asthmatic attacks returned at the same time.

On July 30 he was transferred to another hospital under the care of a specialist in tropical diseases, who again greatly reduced the number of larvae in the stools, this time with gentian violet treatment. There was a simultaneous improvement in his asthma during the period of reduction. It was considered that the asthma was definitely related to the *Strongyloides* infestation. During all this period the sputum was persistently negative for tubercle bacilli on concentration and culture, and *Strongyloides* larvae were not found in the sputum. The *x*-ray appearances had not changed since his admission to Harefield.

Discussion

Pulmonary changes associated with *Strongyloides stercoralis* infestation have been described by Lowe and Lancaster (1944) in their report on 16 cases of strongyloidiasis. Seven of their cases had pulmonary symptoms, four complained of unproductive cough for some weeks, one had been investigated for suspected pulmonary tuberculosis, and one had a small haemoptysis whilst under observation in hospital. Radiographic examination of four patients revealed increased bronchovascular markings. On no occasion had larvae been found in their sputum.

Gage (1911) reported a case in which there were signs of diffuse bronchitis and lobar pneumonia with *Strongyloides* larvae in the sputum. At post-mortem examination the diagnosis of *Strongyloides* pneumonitis was confirmed. Froes (1930) reported a case of pleural effusion in which rhabditiform larvae were discovered before death. Berk *et al.* (1943) describe two cases of strongyloidiasis with pulmonary symptoms. In both cases tuberculosis was suspected owing to cough and sputum, in one case blood-stained, and increased roentgenological markings. Both cases had pronounced eosinophilia. In neither case were larvae recovered from the sputum. In natives with *Strongyloides* infestation for long periods, De Langen and Lichenstein have reported severe asthmatic attacks.

In the case described above, pulmonary symptoms were produced by the infestation. The relationship of the asthma to those periods when living larvae were present in the stools in large numbers is worthy of note. In spite of improvement in the symptoms while under treatment with both hexylresorcinol and gentian violet there was failure to eradicate the infestation entirely.

The significance of the pleural effusion in April, 1946, is difficult to assess. There is no report of larvae in the fluid aspirated at that time, and in the cases of pleural effusion secondary to *Strongyloides* infestation previously reported larvae have been found in the effusion fluid.

I wish to express my thanks to Dr. K. R. Stokes, Medical Director, Harefield County Hospital, for permission to publish this paper; to Dr. John C. Roberts, physician to the Military Unit, Harefield, for advice and criticism and for his invaluable help at all times; and to Dr. F. E. T. Scott, who carried out the bacteriological investigations.

A TIDAL-AIR WHISTLE

BY

F. C. EVE, M.D., F.R.C.P.

The main object of artificial respiration is to produce an adequate tidal air. This whistle, held in the subject's lips, makes his tidal air audible to the operator, the instructor, and the class.

Up till now the ritual of resuscitation has been performed with faith and hope but without evidence that its object was being achieved. Part of expiration might be heard; inspiration was never audible. An instructive instance occurred recently at a meeting held in Beverley before a doctor delegated by the Swiss Red Cross. When the operator, a man with ten years' experience, carried out Schäfer's method the whistle hardly sounded; but when he was replaced by a highly skilled operator it sounded for all to hear. Examiners armed with a whistle could find and remedy many defects.

The whistle is on the bird-call principle, because it must sound during inspiration as well as in expiration—an obvious need for the skylark. It can be boiled, and is easily washed (e.g., in "dettol") each time the subject is changed. It works when its interior is still wet. Counting in seconds—often incorrectly estimated—can now be discarded: timing is done by the whistle to suit the subject's physique. When the inspiratory sound ceases (not before) expiration is induced, and vice versa. If the whistle is obeyed, respirations will not be hurried or jerky. The classes become interesting, and are even amusing. Usually the timing coincides approximately with the orthodox 12 per minute of Schäfer and Silvester. In the rocking method, as it produces a greater tidal air, the longer, smoother whistles call out for a slower rate of about 9 per minute. This is also better for the circulation (4 seconds head-down; 3 seconds feet-down). Tests on larger numbers are needed.

The model has been found to work on all healthy adults and on children of 4–5 stone (25.5–32 kg.), rocked manually. The largest subject was a six-foot (1.8 m.) doctor with a 44-inch (1.12 m.) chest who was rocked for over five minutes, whistling loud and long. He said he was so comfortable that he nearly went to sleep. Yet, when doing his own breathing at rest, the 5-mm. aperture was only just adequate.

Dr. A. A. Harper, of the Physiology Laboratory of Manchester, kindly measured carefully the effect of the whistle in Schäfer's method in two subjects. He found it did not affect the volume of the air breathed, but of course it increased the resistance slightly. The figures were: inspiratory pressure increased from 3.6 to 7.2 cm. H_2O; expiratory increased from 2 to 4.1 cm. H_2O. He considers that these resistances would be of no importance in training conscious subjects. He also allows me to adopt the very convenient nose-clip he used.

Professor E. A. Pask, of the Newcastle Department of Anaesthesia, was good enough to measure the sensitivity of the whistle. With a respiration pump it was just audible at a tidal volume of 200 c.cm. at 8 respirations a minute with a rate of flow of 3.6 litres a minute; or, with a steady flow of oxygen, at 4 litres a minute. He considers it "an instrument of remarkable sensitivity which will be of considerable use in training." In Dr. Harper's subjects the volumes per minute ranged from 6.6 to 7.8 litres with the whistle in Schäfer's method. I am told that the inspiratory note is upper B flat, and expiration usually an octave lower.

The whistle is held in the teeth and closed lips, so that it cannot be applied in cases of unconscious asphyxia. No time-consuming gadgets can yet be authorized where every second is vital. The device is intended to train operators to do their life-saving task efficiently.

At a recent demonstration in London before 130 doctors of the St. John Ambulance Brigade nearly all signified, by a show of hands, their wish to try the method. The tidal-air whistle and nose-clip can now be obtained from Messrs. Siebe Gorman and Sons, Tolworth, Surrey, for a few shillings.

Medical Memoranda

A Case of Twins

The publicity which nowadays is focused on the higher categories of multiple births has caused mere twins almost to escape attention. The following case, however, is interesting enough to be placed on record.

Case Report

The patient was a multigravida aged 26, height 5 ft. 3 in. (1.6 metres), weight 8 st. 5 lb. (53 kg.). Her last menstrual period began on May 1, 1947, and her expected date of delivery was on February 8, 1948. She had one child, a normal full-time delivery on November 10, 1942, weighing 8 lb. 15 oz. (4.05 kg.). There was a history of twins in the family.

In the early months of pregnancy she had some nausea and sickness, which soon improved. At 19 weeks the fundus was two fingerbreadths above the umbilicus. At 23 weeks it reached to midway between the umbilicus and xiphisternum. At 30 weeks the uterus measured 37 in. (0.94 metre) in circumference and 14 in. (35 cm.) in convexity. One small head was felt in the pelvis. *X*-ray examination on November 21 showed twin pregnancy, the first a vertex and the second a breech.

The patient continued to feel well for the rest of the pregnancy, apart from increasing heaviness. Her weight rose from 8 st. 5 lb. to 11 st. 10 lb. (53 to 74.4 kg.). Her highest blood pressure was 136/80, and at no time was there any albuminuria or oedema. She was given iron and calcium during pregnancy, and was admitted for rest one week before term.

On admission both foetuses presented by the vertex. The foetal heart rates were 136 and 142. Measurements of the uterus were : circumference 46 in. (1.16 metres) and convexity 23 in. (58 cm.).

A medical induction was contemplated at term, but at 10.30 p.m. on February 8, 1948, she went into labour. At 5.30 a.m. the next day the os was fully dilated, and at 7.30 a.m. she was delivered spontaneously of a living male infant, weighing 10 lb. 0¼ oz. (4.54 kg.) in the R.O.A. position. After 20 minutes pains restarted, and 15 minutes later a second living male infant, weighing 8 lb. 3 oz. (3.71 kg.) was born in the L.O.A. position. Twenty-five minutes later the placenta and membranes were expelled intact, the total length of labour being 10 hours 25 minutes. There was a loss of 18 oz. (510 ml.). The placenta was binovular in type and weighed 3 lb. 15¼ oz. (1.8 kg.)—i.e., little less than one-quarter of the combined weights of the infants.

The puerperium was entirely uneventful. Both infants had regained their birth weight by the seventh day, and by the tenth day the larger one took 18 oz. of milk from the breast, and the smaller one 14¾ oz. (420 ml.). Neither took less than this in 24 hours during their subsequent days in hospital. Residual milk expressed was 3¾ oz. (106 ml.), making a total yield of 36 oz. (1.02 litres) of breast milk on the tenth day.

The babies were fed simultaneously at all feeds, and were discharged on the 19th day, fully breast-fed, and weighing 10 lb. 1½ oz. and 8 lb. 9 oz. (4.58 and 3.88 kg.) respectively. The mother had the antenatal preparation of the breasts which is practised at this hospital (Waller, 1946), and during her lying-in needed no more help than the usual care and patience of the nursing staff.

Throughout her pregnancy she was well, and she carried the babies to term, a comparatively uncommon event in twin pregnancies. The records of this hospital show only 14 instances out of 67 twin deliveries in the past four years.

Hospital	Year	No.	Average Weight		Heaviest Weight	
			Twin 1	Twin 2	Twin 1	Twin 2
			lb. oz. kg.	lb. oz. kg.	lb. oz. kg.	lb. oz. kg.
Queen Charlotte's ..	1945	19	5 6 2·44	5 9 2·52	7 9 3·43	8 8 3·85
Guy's ..	1946	17	5 1 2·29	6 1 2·75	8 2 3·68	6 12 3·06
Liverpool ..	1944	28	5 2 2·32	5 7 2·47	7 0 3·18	7 6 3·35
Camborne ..	1945	6	6 3 2·81	5 11 2·58	6 15 3·15	7 7 3·37
B.H.M.B., Woolwich	1944	17	5 0 2·27	5 3 2·35	6 6 2·89	7 3 3·26
" "	1945	20	4 10 2·10	5 3 2·35	6 4¼ 2·84	7 4 3·32
" "	1946	11	6 0 2·72	5 12 2·61	7 11 3·49	6 8 2·95
" "	1947	19	5 3 2·35	4 5 1·96	7 4 3·29	7 7 3·37

As will be seen from the accompanying table, the average weights of twins, taken from several different hospital reports, range between 5 lb. and 6 lb. 3 oz. (2.27 and 2.81 kg.). The heaviest weights recorded in the series were 7 lb. 9 oz. and 8 lb. 8 oz. (3.43 and 3.85 kg.) at Queen Charlotte's Hospital in 1945.

Progress has been consistently good. Breast-feeding was maintained, apparently without strain, for eight months. At 3 months the babies weighed 13 lb. 8 oz. and 11 lb. 9¼ oz. (6.12 and 5.26 kg.). They had had no illnesses and were free from any sign of rickets. The haemoglobin level was found to be 60% in both cases, and iron was prescribed. When last seen on October 7 (aged 8 months) they weighed 22 lb. and 20 lb. 8 oz. (9.98 and 9.3 kg.) respectively and were very healthy.

My thanks are due to Mr. Keith Vartan, medical director, and Dr. Harold Waller, honorary paediatrician, for permission to publish this case and for their help and advice.

Aileen P. M. Dring, M.B., B.S., D.R.C.O.G.,

Congenital Pyloric Stenosis in Three Successive Male Babies of the Same Parents

The following cases are reported in the belief that it is rare, if not unique, for the same parents to have three consecutive male babies suffering from congenital pyloric stenosis. It would be interesting to know if any readers have had similar experiences.

Case Reports

Case 1.—This occurred in July, 1945. The precise clinical details are lacking except that the condition was diagnosed clinically and confirmed at operation. The child died shortly after the operation. It is believed that the general condition had greatly deteriorated before consent was given by the parents.

Case 2.—This occurred in July, 1947. The clinical features were classical in that projectile vomiting started at the end of the second week after birth. Visible peristalsis and a palpable mass were evident. Unfortunately, however, the family conditions left something to be desired, and the parents did not use the "eumydrin" with which the doctor was treating the case. Other therapeutic measures were carried out by the parents against the doctor's advice and operation was refused. Inevitably the general condition became worse, and when eventually the parents realized the folly of their ways the child died before operation could be performed. A post-mortem

examination was, however, carried out and a greatly hypertrophied pylorus was found with complete stenosis.

Case 3.—This occurred in July, 1948. The child was a male and the projectile vomiting started towards the end of the second week. Visible peristalsis and a palpable mass were again found after feeding. Treatment with 1/750 gr. (0.875 mg.) of eumydrin before feeds was begun, and from the outset the condition was good. On this occasion co-operation from the parents was forthcoming and it was possible to carry out a Rammstedt operation in the early stages. Recovery was rapid and uneventful.

Congenital Pyloric Stenosis in Binovular Twins

The aetiology of congenital pyloric stenosis is quite obscure. The constant pathological findings and the onset a few weeks after birth point to some defect in the development of the pylorus, widely assumed to be dependent on a genetic factor.

Individual reports of the disease in two or more siblings have appeared from time to time (Parker, 1927; Bilderback, 1928; Cockayne, Moncrieff, and Sheldon, 1928; Thompson and Gaisford, 1935; Fabricius and Vogt-Müller, 1937; Donovan, 1938; O'Donnell and Klein, 1941; Cathala and Cler, 1944; Marquezy, 1944; Kaufman, 1947). On the other hand, Akin and Forbes (1947) found only three instances in 147 patients, Nafe (1947) six cases in 129 patients, and Gavois and Poyanne (1944) one case in 67 patients. It is clear that it is unusual for siblings to be affected, although Cockayne and Penrose (1943) concluded, after a most exhaustive investigation, that there was a definite though small familial incidence.

Occasionally pyloric stenosis has occurred in successive generations. The father of the female patient reported by Donovan (1938) had undergone operation for stenosis when a few weeks old; one of Nafe's (1947) patients had an uncle who had had the disease, as had the maternal aunt of the pair of twins reported by de Lange (1936). Schrieber (quoted by Laubscher and Smith, 1947) described a patient whose father and grandfather both suffered from pyloric stenosis in adult life, which was believed to be of congenital origin. Caulfield (1926) cited a further case that was even less convincing. Cockayne (1934) reported two pairs of twins who were first cousins, all of whom had the disease. The absence of any definite hereditary characteristics does not lend support to the genetic theory, but if a Mendelian recessive was concerned it would remain concealed for long periods, showing a tendency to exposure particularly on intermarriage; and in respect of this Cockayne and Penrose (1943) found the proportion of patients with consanguineous parents exceeded random expectation.

Laubscher and Smith (1947), in a recent review on congenital pyloric stenosis in twins, found it recorded in 13 monovular twins; in 11 of these both twins were affected, while Sheldon (1938) and Lasch (1925) each noted an exception. In 24 sets of binovular twins there were two instances in which both were affected. Laubscher and Smith (1947) reported binovular male twins, both of whom underwent operation five weeks after birth, and O'Donnell and Klein (1941) recorded a similar occurrence; Nafe (1947) mentioned that he had recently seen binovular twins operated on for pyloric stenosis on the same day.

Case Reports

The mother, a 2-para aged 33, gave birth to a male child on June 29, 1948; simultaneously the membranes of the twin were artificially ruptured, but the uterus became inert and the second child, a female, was not born until July 1. There was an elder child, a girl aged 6. No history was elicited of any similar trouble either in the mother's or in her husband's family, and the parents were not related.

First Twin.—Male, born June 29, 1948; birth weight, 6 lb. 2 oz. (2.78 kg.). He was breast-fed for the first fortnight, but then changed to a proprietary food. He thrived until July 21, when he vomited after one of his feeds. Three feeds later he vomited again, and thereafter following every bottle: the vomitus became large in quantity and projectile in nature. On July 23 he was admitted to Queen Mary's Hospital in a dehydrated condition, and weighing 5 lb. 3 oz. (2.35 kg.). A palpable tumour lay under the right costal margin, with visible peristalsis in the epigastrium. On July 24 the abdomen was explored under local analgesia. A firm pyloric muscle tumour was found, and a typical Rammstedt's operation was performed. The child made an uneventful and rapid recovery.

Second Twin.—Female, born July 1, 1948; birth weight, 4 lb. 2 oz. (1.87 kg.). She was maintained in an oxygen tent for five days, with three-hourly oesophageal feeds of a proprietary food. After a further three weeks in the premature baby nursery she was discharged home, on July 25, weighing 5 lb. 8 oz. (2.49 kg.). For a few days she continued to progress favourably, but on August 1 suddenly vomited after a feed, and thereafter shortly after every bottle; with each vomitus a large quantity was ejected in projectile fashion. On August 3 she was admitted to the Connaught Hospital because of an outbreak of whooping-cough at Queen Mary's Hospital. She weighed 4 lb. 1 oz. (1.84 kg.), but was less dehydrated than her brother had been. Peristaltic waves crossing the epigastrium were easily visible; and a mobile tumour was palpable under the right costal margin. She was given a feed and shortly after it was forcibly vomited. On August 3, under open ether anaesthesia, a Rammstedt's operation was performed for a typical congenital hypertrophied pylorus. Her post-operative progress was quite uneventful and she rapidly gained in weight.

Comment

A study of the published data, together with such cases as the one reported here, reveals the following: (1) the disease may occur in siblings, but with relative infrequency; (2) it is rare for two or more generations to be involved; (3) whilst each twin is usually affected when of monozygotic origin, authentic exceptions have been recorded; (4) there have been several instances in which each twin of dissimilar pairing has been affected, such as the example reported here.

Reviews

A STUDY OF SICK SOCIETY

Psychosocial Medicine. By James L. Halliday, M.D., D.P.H. (Pp. 277. 17s. 6d.) London: William Heinemann Medical Books. 1948.

It has been clear for some time that this book was an unusual one. Since its appearance in the United States last year American colleagues have been asking, almost monotonously, how Halliday's book is being received. Last autumn, when Mr. Aldous Huxley interviewed the Press shortly after he arrived in this country, it was reported that the discussion turned to Halliday's book on psychosomatic illness, and more recently it appeared as the subject of a 20-minute talk in the third programme by Professor L. J. Witts. Its subtitle, *A Study of the Sick Society*, gives the clue to this wide interest, and here, indeed, is a disturbing picture of some of the sicknesses of the communities, and of the subgroups within them, of which we ourselves are so intimately a part.

The main theme may be put thus. Although the mechanismic outlook of nineteenth-century medicine led to brilliant advances against many physical illnesses, it diverted attention from other important aetiological factors, with the result that what are now called the psychosomatic illnesses have been getting progressively more common. It is not only that the total figures are rising. Halliday's essential point is that many of these illnesses have shown within the last few decades changes in their incidence in different age, sex, and occupational groups. For instance, peptic ulcer would appear to have changed from being an illness chiefly affecting young women and middle-aged men to one that is now more typical of young men and middle-aged women; or, again, the mining group in recent years has shown a higher rate of illness than other industrial groups. Furthermore, certain other features—e.g., infertility and suicide rates—have shown similar trends. According to Halliday, these findings can be accounted for only by social psychological factors, and he therefore suggests that such objective measures should be taken as indices of the sickness or health of any group or society. (It is because "social" medicine means in practice the measures designed to keep populations, or aggregates of people, from becoming sick through physical causes that he reluctantly adopts the term "psychosocial" to ensure that the psychological factors are included.) Halliday next takes the daring view that, when these indices are rising in a group, that group is in danger of a devitalizing biological change which can readily progress until the group is extinguished by failure to produce and to reproduce.

Having diagnosed the faults within the social sphere, the author goes on to suggest that medicine will have to be reintegrated with the social sciences and with politics, and that those doctors who effect this synthesis within themselves will become the pioneers of new ways in medicine which will lead us out of the present increasing specialism with its impotence in face of the most prevalent disorders in modern industrial society.

It is almost impossible to comment briefly on the condensed thought in this book. The first task, as the author himself suggests, will be to carry out further studies to confirm and to expand his findings, and to ascertain how fully all the relevant factors have been considered. To take one instance, in quoting the unduly high rates of hypertensive disorders in miners' wives the possible effects of this group having a relatively higher average age than other groups of wives does not appear to have been allowed for. More social anthropological data will be required, too, on the individual histories of the sick groups, for occupational groups are wont to have quite marked food habits. But even before this checking up has been done it is difficult not to be impressed by the apparent psychosocial aetiology of some of the disorders mentioned. The history of miners' nystagmus is an excellent example of how too rigid an adherence to physical aetiology can blind us to the most relevant facts. If only a few of the main findings about the changing distributions of the psychosomatic illnesses are eventually accepted, serious thought will have to be given to the whole status of psychosocial factors in medical thought and practice; it will be difficult to "explain" these by such concepts as "bad nutrition" or "hereditary factors."

It may well be that medical historians of the future will write of this book as one of the important contributions to medical thought in the twentieth century. Almost every page reveals the unusual insight of the author and his capacity to analyse and synthesize the implications of his theme, so that there is the stamp of genius about the work as a whole. It is significant that the insights of the poets have evidently made deep impressions upon the author, and some of his views may be rejected for a time as poetic rather than scientific. That, however, will illustrate the author's view that it is not easy for us to face up to some aspects of our present society. In fact, one of the best object lessons in understanding psychosocial forces will be to watch the reception and fate of this book within the next few years by different professional groups, and to understand why it has stimulated some groups and made others anxious, as it almost certainly will do.

The appearance of *Psychosocial Medicine* is peculiarly well timed. One of the features of psychosomatic illnesses upon which the author comments is their tendency to be exacerbated by actions taken by doctors which show that they do not really understand their origins. Unless effective ways of combating these disorders can be developed there is bound to be a rise in their incidence and chronicity, so that the burden on the new Health Service will increase steadily; no national health service can afford to ignore Halliday's considerations.

As a final point, the reader can speculate on whether it was a sickness of some of the groups in our British society which led to this fundamental book being produced in America and so to making a Glasgow physician write about "gasoline engines."

J. D. SUTHERLAND.

B.C.G.

B.C.G. Vaccination in Theory and Practice. By K. Neville Irvine, D.M. With foreword by Konrad Birkhaug, M.Sc., M.D. (Pp. 130. 9s. 6d.) Oxford: Blackwell Scientific Publications. 1949.

This is an excellent little book, written for the practical man who is going to use B.C.G. and wants to know the "why" and "how." It is well documented, and the references, which are given at the end of each chapter, number over 500. The author covers the history and present methods of producing the vaccine, discusses its safety, describes in detail alternative methods for the vaccination of human beings, reviews the experimental and field evidence on the protective value of B.C.G., and ends with a brief discussion on its best mode of use in Great Britain. He gives a good deal of space to the safety of the vaccine, pointing out that all the adverse reports, whether in animals or in man, date from before 1930. He believes that about that time potentially virulent variant organisms were eliminated from the vaccine and that now the danger is that the strain may become too avirulent to afford adequate protection. The safety of B.C.G. is attested by the fact that some ten million persons have been vaccinated with it and, apart from the Lübeck disaster, only 37 cases of tuberculosis have, rightly or wrongly, been attributed to its use.

The real question to-day is not whether B.C.G. is safe but what is its protective value in different age groups of the population and among people of varying levels of genetic immunity. Before recounting the investigations made to determine this the author lays down seven minimum postulates for a field trial if it is to be accepted by the statisticians. Whether it will be possible to carry out a properly controlled trial in this country is doubtful, but there seems no reason why one should not be attempted if the Ministry refrains from distributing the vaccine indiscriminately.

It would be interesting to know why the author has ignored the negative results of the large-scale use of B.C.G. by Blanch,

Blanch, and Lieutier in Uruguay. Little attention has been paid in the literature to these findings, and Dr. Irvine, who has gone to considerable trouble to make certain of many of his facts, might well pay a visit to South America to find out the real truth about them. Another point that needs investigation is the need for segregation of children in tuberculous families before and after vaccination. Dr. Irvine recommends the approved practice, but there seems to be an increasing tendency in some countries to dispense with it. What we really want to know is whether Rosenthal in Chicago and Levine and Sackett in New York are both right. Is it true that B.C.G. with segregation protects and without segregation it does not?

Throughout the book the author is simple, sane, direct, and objective. Only occasionally does he lapse. For example, in his final discussion he summarizes an earlier section in these words: "This chapter shows that vaccination does produce a definite resistance in man; the degree produced appears to be 70–100%." What does this mean? It cannot mean what it appears to mean—namely, that without vaccination 70–100% of the vaccinated persons would have developed tuberculosis. What the author probably means is that vaccination protected 70–100% of the small proportion of the population that would have developed tuberculosis had they not been vaccinated—which is a very different thing. It is to be hoped that in a future edition the original statement, which may be quoted away from its context, will be revised. Again, on page 93 the author quotes Hertzberg as saying, "For primary tuberculous lesions the ratio of the vaccinated morbidity rate to that of the controls is 1:137," and follows this up with the statement: "Neiman and Loewinsohn, in a radiological study of 1,417 vaccinated children and 1,414 controls, found the ratio per 1,000 person-years to be 1:2.83." Surely an explanation is required of these totally discrepant findings.

In recommending the wider use of B.C.G. vaccination Dr. Irvine makes it clear that it should be used as an addition to our antituberculosis measures, not as a replacement for any of them. Most workers will agree that so long as this is firmly borne in mind there is a place for B.C.G. vaccination in this country.

G. S. Wilson.

LEWIS'S CARDIOLOGY

Electrocardiography and Clinical Disorders of the Heart Beat. By the late Sir Thomas Lewis, C.B.E., F.R.S., F.R.C.P. (Pp. 285; illustrated. £1 5s.) London: Shaw and Sons. 1949.

It is almost superfluous to review a book by the late Sir Thomas Lewis, for there is no medical writer of the last generation who has transmitted to paper in such clear prose work of such a high standard. The present book is a combination of two previous volumes, *Clinical Disorders of the Heart Beat* and *Clinical Electrocardiography*. It was completed just before the author's death, and, as is said in the preface, he felt that the time had come for integrating the subjects into one volume. This book is one which must necessarily be included in the libraries of medical institutions and which should be at hand for reference by all cardiologists. This is not only for historical reasons but because the clear sentences of the book contain a fund of valuable and stimulating information, some of it with a very clear personal ring.

It is always possible for a reviewer to read his volume with jaundiced and hypercritical eyes, and, even in the case of writings by Sir Thomas Lewis, minor points of criticism can be found. For example, on page 6 it is advised that the subject whose electrocardiogram is being taken should be in a sitting position. It is my experience that the broader and more comfortable the couch the freer the tracing from muscular interference. On page 21 are given three normal curves taken from lead III in different subjects. One of these could easily be that of a patient who had previously suffered from a posterior coronary infarct. On page 58, where a curve characteristic of Fallot's tetralogy is shown with marked right axis deviation, the characteristically sharp P wave, which is also well defined, is not remarked upon. However, these are small samples of the hypercritical attitude already referred to.

There are certain broader criticisms which can be justifiably added. The book makes little mention of the direct chest leads, and where these are referred to the information is usually restricted to the curves shown by CR4. With the great advance in electrocardiography and the advent of the school which already prophesies the complete disappearance of the three standard leads, it is clear that this omission, so far as electrocardiography is concerned, is a serious one. But such omissions are inseparable from the passage of time, and they do not in themselves constitute criticism of the book. For students who desire a work on cardiology as a book of reference this monograph is not in itself sufficient, for there is no section on cardiac radiology.

When these remarks have been made, it still remains a fact that the description of cardiac irregularities, which are dealt with seriatim in separate chapters, remains classical both in presentation and subject-matter. It is sad, however, that there is no wide, comprehensive textbook on cardiology from the hand of the man who was in so many senses the father of his subject.

ESSAYS IN PSYCHO-ANALYSIS

Searchlights on Delinquency. Edited by K. R Eissler, M.D. (Pp. 456. 30s.) London: Imago Publishing Co. 1949.

These psycho-analytic studies on delinquency are dedicated to a remarkable man, August Aichhorn, a Viennese educationist who devoted himself to the study of delinquent youth and eventually found in psycho-analytical teaching the framework he required for understanding his patients and treating them. He was apparently a strong pacifist, and in 1907 successfully exerted his influence against intrusion of the military spirit into education. He later founded an institution for delinquent boys, with whom he had extraordinary success. This institution foundered during the last war but has since been re-established, and Professor Aichhorn's work has been honoured by his election to the presidency of the Viennese Psycho-analytic Society. The editor of this symposium writes of him as an artist in technique, a unique teacher, and as having uncanny intuition. He can "reconstruct the whole of a human personality from a few meagre details which seem only trifling superficialities to the unintuitive." He will spend time arguing with a schizophrenic adolescent about the interpretation of an obscure passage in the Bible, with the result that, week by week, the patient recovers. Even his psycho-analytical colleagues emphasize how much of his success is attributable to personal factors. They have contributed to this book many scholarly articles which will be of great interest to analysts practising in this field.

Eliot Slater.

THE RETICULOSES

La Réticulose Histiomonocytaire. By P. Cazal. (Pp. 196. 350 francs.) Paris: Masson et Cie.

Reticulosis and Reticulosarcomatosis. By P van der Meer and Dr. J. Zeldenrust. (Pp. 83; 21 figures. 40 florins.) Leiden: Universitaires Pers Leiden. 1948.

Dr. P. Cazal's monograph is worthy of study by all who are interested in the reticuloses. The author defines the condition he is describing as including those reticuloses which pursue a rapidly fatal course, and which may under certain circumstances produce a leukaemic blood picture. Letterer-Siwe disease and histiocytic medullary reticulosis are included in this definition. He describes in considerable detail the manifestations of the disease process throughout the body, and his references to abnormal blood pictures are of particular interest, for he develops the thesis that proliferation of histiocytic cells in the tissues may appear in the blood stream as cells of the monocytic series, either well or poorly differentiated. The suggestion is put forward in connexion with the pathogenesis of this condition that it represents a multifocal disease rather than a malignant tumour spreading by metastasis.

The author's opinions are best summarized by quoting his final sentence: "Reticulose histiomonocytaire: maladie caractérisée par la prolifération métaplasique (c'est-à-dire envahis-

sante, Irréversible et s'accompagnant d'atypie cellulaire) et systématisée des cellules réticulaires et histiocytaires qui peuvent soit rester sur place, soit passer dans le sang sous forme de monocytes plus on moins typiques." Despite the fact that some of the views put forward in this monograph may not be fully acceptable to all workers, a most stimulating contribution to a confused subject has been presented.

The work of Drs. van der Meer and Zeldenrust from the University of Leiden sets out to present a clinico-pathological account of diseases of unknown aetiology associated with the reticulo-endothelial system. Little new in this confused field of study is presented, and the review of literature is largely confined to that coming from the Continent, American contributions being largely ignored. The fundamental concept is retained which divides diseases of supposedly hyperplastic origin from those which are thought to be true malignant tumours and applies the separate titles reticulosis and reticulosarcoma to them. No new evidence, either clinical or pathological, is presented to substantiate this claim, however.

The reticuloses are described as acute or chronic, but little attempt is made to correlate this clinical subdivision with pathological entities. Reticulosarcomata are described as being localized or generalized, but no stress is laid upon the prognostic significance of these varieties. The authors' presentation suffers from an inadequate English translation which makes it difficult sometimes to follow their reasoning.

GEORGE LUMB.

MODERN PRACTICE IN PSYCHIATRY

Modern Practice in Psychological Medicine, 1949. Edited by J. R. Rees, M.D. (Pp. 470 and an Appendix. £2 10s.) London: Butterworth. 1949.

The editor explains that this well-produced volume is intended for medical students and general practitioners, not for specialists in psychiatry. He has invoked the aid of twenty-eight collaborators with widely different backgrounds and viewpoints, who have contributed essays on the topics assigned to them. The result is a most uneven production with much overlapping and repetition and some regrettable omissions. The treatment recommended varies, and sometimes flatly contradictory opinions are expressed. Difficulties of this kind are likely to arise in any symposium in default of the most rigorous editorial planning and pruning, but they are specially likely to arise in a relatively short volume on psychological medicine which covers an undefined field without proper delimitations between the different parts of it.

In view of the title the medical student and general practitioner may reasonably expect to find clear guidance on practical problems of diagnosis and treatment, but both may be excused if at times they feel baffled and bewildered by the work. In particular, the therapeutic implications of expositions in terms of "dynamic" psychopathology are puzzling to the reader, for they seem to lead to the deduction that patients should be analysed, which, it is then pointed out, is for the specialist. The chapter on physical methods of treatment is disappointing: and what is the beginner likely to make of such *obiter dicta* as that of Dr. Brock Chisholm, who identifies "amongst factors that commonly tend to slow, to distort, or to prevent satisfactory mental and social development . . . teaching of children to believe in the reality of phantasies such as fairies and Santa Claus. . . "?

In brief, the book does not fulfil its intended purpose, as a random collection of essays on psychiatric topics can scarcely be expected to do. Yet in spite of the lack of editorial planning both student and general practitioner could gain much from it, for in parts the symposium is not only good but excellent. The section on sexuality and the sexual disorders, by Professor D. Ewen Cameron, and that on psychosomatic medicine, by Dr. E. D. Wittkower, both contain much interesting matter; while among many valuable essays "Nature and Nurture—The Factor of Inheritance," by Dr. Eliot Slater (which is all too short), "Psychiatry and Neurology," by Dr. Russell Brain, "Mental Deficiency," by Dr. E. O. Lewis, and "The Schizophrenic Disorders," by Dr. Hunter Gillies, are outstanding.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY OCTOBER 1 1949

DISTINCTION AWARDS FOR CONSULTANTS

When the report of the Spens Committee on the remuneration of consultants and specialists was published in June, 1948, we criticized the suggestion for special awards as "the one outstandingly unsatisfactory proposal in a report which is likely to commend itself to those who work as consultants and specialists in the new Service." We expressed the hope that consultants and specialists would give their opinion on this matter so that it should not become accepted policy merely by default. There was at the time little response to this suggestion, but now that groups of consultants all over the country are being invited by the Distinction Awards Committee to select suitable candidates from among their colleagues, consultants, as is clear from our correspondence columns, are beginning to voice some disquiet. In a letter to this *Journal*[1] Dr. F. M. R. Walshe pungently expressed what a number of consultants in this country probably think about the proposed method of distributing what have been misleadingly called prizes. They are pensionable increments to income. Dr. Walshe has found support for his views, not least in the letter which appeared in the *Journal* of August 27 signed by 19 members of the consulting staff of a teaching hospital, who expressed the hope that "it is not yet too late to abandon the idea of distinction awards in its present form." A cold note of caution was sounded by Dr. H. E. A. Boldero, who stated that there is no alternative to the present method of distributing these distinction awards to consultants. He writes: "I speak from the book when I say that there will be no substitute. Money for these awards will not be available for any other purpose, such as an all-round addition to basic salaries." Dr. Boldero no doubt weighed his words carefully, though one may presume that the final authority in these matters is the Minister of Health. It may well be true that no other alternative will be accepted by the Minister, and that on grounds of common prudence the profession would not wish to make any move which would diminish its total income. But it must nevertheless take into account the views of those young consultants who through these columns have expressed their distaste and apprehension of the present scheme of making the Spens awards. If no alternative can be found, then with good grace we must accept the second best.

We suggested over a year ago that the additional money available should be attached to posts in the new hospital service demanding men of the highest calibre. The new hospital and consultant service is still in a formative period. Those responsible for its working have been overwhelmed with problems of organization, and little constructive thought has yet been put into the development of hospital policy. Some constructive proposals were made in a special number of the *Practitioner* by the writer of the article "The Surgeon and the Service." He suggested, for example, that a small group of senior men should have the task of co-ordinating the surgery of a region or district "by advice, by telling one hospital of the work being done at another, by advising on particular cases, and by informing regional headquarters where, and by whom, good work is being done." As the hospital service evolves one would have thought that some such idea as this would gather force, and that in each region there would be room and need for outstanding consultants in medicine, surgery, obstetrics and gynaecology, to carry out the work suggested by the writer in the *Practitioner*. Similarly, there are other jobs requiring long training and highly developed skill such as neurosurgery and thoracic surgery which will spread over one or more regions. Such posts demanding special responsibility or special skill are bound, we suggest, to be created in the National Health Service, and it is an obvious corollary that to these posts, whether whole- or part-time, there should be attached salaries higher than what has been called the basic salary for the ordinary consultant and specialist. For such special posts there would be keen and open competition and open selection.

If the profession has to accept the present scheme then it must look very closely into the method now being adopted. It has been suggested to the chairmen of medical committees of teaching hospitals that three or four members of each committee should meet in secrecy to decide who among their colleagues should be graded first, second, or third class, and to forward their recommendations to the Distinction Awards Committee. We understand that outside teaching hospitals the suggestion has not been made to the Regional Hospital Boards but to the Assessment Committees, whose decisions on grading have already come in for a certain amount of criticism. Whether the criticism is justified is beside the point. These groups of consultants all over the country being asked to grade their fellow-consultants in secrecy are being placed in a highly invidious position. Clearly they cannot recommend themselves, and it may be presumed that the Central

[1] *British Medical Journal*, August 13, p. 383.

Distinction Awards Committee will find it difficult not to give them awards, because they have already been put into the position of judges and therefore acquiring merit. The Central Committee will have the difficult task of deciding who among the selectors in the regions are to receive the first, second, or third prize, the men themselves feeling no doubt that they are meeting together as equals. There is surely something distasteful in the issuing of confidential reports on colleagues who will remain in ignorance of what is said about them. Granted that it would be possible in such a varied profession as medicine to weigh the merit of one kind of worker as against another kind, to assess for example the merits of a professor of bacteriology as against those of an abdominal surgeon, what criteria are to be adopted to guide those faced with this almost impossible task? At its meeting last week the Central Consultants and Specialists Committee, uneasy about the situation, decided at once to look into this question. If there is to be an attempt to assess merit, then there is much to be said for what appears at first to be a fanciful suggestion put forward by Mr. Frederick Ridley in the *Journal* of September 3—namely, the award of marks for certain distinctions already held by those eligible for the Spens awards. The essential thing is to adopt some method that will eliminate as far as possible the bias of judgment which any medical man must inescapably have in relation to a colleague who practises the same profession. To pretend that bias will not operate is to ignore an obvious but unpleasant fact. To find a method of eliminating bias which is as objective as possible should be the first task of the Distinction Awards Committee, so that some uniform method of assessment can be adopted all over the country.

We have no doubt that the Committee will perform its arduous duty with all the efficiency and impartiality it can bring to bear on it. But to adopt a *laissez-faire* attitude to the Distinction Awards would, we are convinced, be a disservice to medicine, because what is decided now will have an important influence on the healthy evolution of the Hospital and Consultant Service of Britain. *Reculer pour mieux sauter* is a sound adage.

A YEAR OF N.H.S.

"How is the National Health Service working out?" is one of the first questions a foreigner will put to a British doctor. And the usual answer is, "It is far too early to say." In any case the British doctor is so deeply immersed in it, and incidentally so overworked, that he is little inclined to concern himself with the generality of things; the particular overwhelmingly engrosses him. The extra number of the *Practitioner*, just published, has therefore performed a timely service in attempting to review the "first year's working." This it does in a series of articles the value of which is somewhat diminished by the fact that they are anonymous. This in itself is a portent. Men working in a "service" hesitate to put their names to anything in the nature of a criticism of it. The same tendency may be seen in the correspondence columns of this *Journal*. The real danger of a service in which men and women are employed by the State—or, at least, paid by the State—is that they will tamely acquiesce in things they dislike, or hesitate to put their names to forthright criticism. This may lead, in Medicine, to a sapping of that essential of democracy—free discussion. The editor of the *Practitioner* considers that anonymity is essential "when the chief concern is that writers should speak their mind with complete freedom, uninfluenced by the desire to please their friends or placate their enemies, to escape the labels of 'traitor' or 'reactionary,' and when, as in several instances in this number, the article is a symposium embodying the views of several men." It is a sad and sorry comment on Medicine to-day to admit that only under the cloak of anonymity is it possible to speak the mind with complete freedom on what the same editorial describes as "one of the greatest ventures in the history of medicine."

One aspect of this great venture is looked at in the article reviewing the Service as a whole—the difficulties placed in the way of the private patient needing hospital treatment. The charge per hospital room for the private patient has greatly increased, and "when it was found that in many hospitals the private beds were by no means full the regulation was made that at least one-third of the private beds should be allotted as amenity beds for patients applying for treatment through the Service." This, according to the same article, "led several busy consultants to take more of their work to private nursing-homes." It is suggested that this tendency will increase unless the official attitude to the provision of private-patient beds in hospitals is changed. Yet the writer of the article on "The Physician and the Service" states that "the so-called 'amenity beds' allowed for in the new scheme of things are noticeable only by their absence." He, too (or they?), notes (or note?) that the nursing-homes are well filled. The author of the stimulating article "The Surgeon and the Service" considers that the "position of the teaching hospitals as consultative centres, in England at any rate, appears to have deteriorated within the past year." The beds, he states, are blocked by the chronic sick; the out-patient departments are no longer "courts of appeal" but tend to become "routine clinics"; "radiodiagnosis is worse in quality"; pathological reports are "less informative, accurate, and reliable." This, he

considers, is largely due to an increase in routine work, but is in part "due to the fact that the workers are now 'ten-to-five office doctors' who have little personal interest in their relations with the clinical staff or their patients." There is in the *Practitioner* symposium no article by a radiologist, or a pathologist, or a biochemist, or a bacteriologist against which one can offset this criticism, which reads as if it were the experience of one observer rather than a fair commentary on the experience of hospitals generally. The writer voices a complaint, surely widely held, about the amount of time spent on paper work and on committees, commissions, and advisory boards. He complains, too, of the drastic reduction of the senior surgeon's income. "He may still charge no more than a junior may charge for removing a ruptured appendix." And he finds—as so many others find—that "the prospect of being rewarded according to the assessment of a witenagemot of worthies, instead of, as heretofore, in proportion to the place they have made for themselves, is humiliating."

The physician seems to be less alarmed about his financial status than is the surgeon: "Incomes," he writes, "are about back to what they were." He notes that the departments of pathology, cardiology, and physiotherapy have been grossly overloaded with work —"one of the best examples of how the haste in which the Service was introduced has led to confusion." The obstetrician, in his contribution to the symposium, seems less concerned about remuneration than are the physician and the surgeon, though he, too, deplores the financial obstacles placed in the way of the use of the private bed in hospital. He devotes (or it may be "she") much of his article to advocacy of the proposals for a national maternity service published by the Royal College of Obstetricians and Gynaecologists in 1944. He repeats the familiar and accepted criticism that, with the general practitioner responsible to the executive council, the midwife to the local health authority, and the obstetrician to the regional board or board of governors, co-ordination of work is difficult. An attack is made on the "general-practitioner obstetrician wielding the forceps . . . because of sheer financial necessity imposed on him by the workings of the Health Act." This is a matter to which we shall return in a subsequent issue, content to observe here that if there is any justification in the attack it is the biggest condemnation there could be of the failure of obstetricians to instruct students properly in the teaching hospitals of this country.

The "country practitioner" and the "town practitioner" are at one in noting the great increase of work falling on them as a result of the National Health Service. In this they are supported by the author of the article "The Ministry and the Service"—presumably an officer of the Ministry of Health, for who else could write with knowledge? This work has increased both in densely populated areas and also in places where private practice used to predominate, "as the patients made greater demands in proportion to their numbers." In the same article it is stated that more than 95% of the population are using the Service and the same proportion of general practitioners have entered it. Similar evidence of increased work comes from the writer(s) of the article on the Service in Scotland, with the observation that "only the absence of a major epidemic last winter enabled busy practitioners to struggle through at all." Along with this overwork is a well-founded anxiety that general practice is losing much of its savour. The country G.P. refers to the "strong temptation to refer a patient early instead of sharpening one's wits upon the case." On his exclusion from the cottage hospital, he observes that "no doctor of any character will be content for the rest of his days just to dance attendance on specialists or consultants as a 'clinical assistant,' particularly when in many instances he has had more years of practice than the 'specialist' has had of life." The town G.P. echoes this thus: "The general practitioner wants to feel he is actively engaged in *medicine* rather than providing a sort of clearing station for the disposal of cases." Two newly qualified practitioners, giving the viewpoint of the "young doctor," note that "the ideal of general practice is now under a cloud; he cannot be physician, adviser, and friend of his patients." They observe that many who formerly would have made "good and happy general practitioners have entered a field where they will be only lukewarm specialists." And from Scotland comes the warning that the general-practitioner service "must not be allowed to deteriorate into the last resort for disappointed hospital trainees." The growing unattractiveness of general practice is the most serious repercussion of the National Health Service on the development of medicine in Britain.

It is not easy to sum up the impressions gathered from the *Practitioner's* symposium. Several writers deplore the haste with which the Service was introduced and regret that the advice to bring it in by stages was ignored by the Minister of Health. For this he gave his own reason in an interview with Mr. John W. McPherrin, editor of the *American Druggist*, a recent issue[1] of which was devoted to an examination of the National Health Service. As reported, Mr. Bevan said: "To do it gradually, piece by piece, step by step, would create many resistances and make the Minister subject to everyone else instead of having them subject to him. It is his responsibility to make the new system work, and he cannot do that if he is not master, if he does not have complete control." In the symposium surveyed briefly above there emerges the picture of a profession doing

[1] *American Druggist*, July, 1949, p. 92.

its harassed best to make the National Health Service a going concern. Mr. Bevan's haste and mistakes have to a large extent been masked by the self-discipline of the individual doctor, whose adherence to the traditions of a learned profession makes it possible for him to withstand the vagaries of the political climate. But the Minister—and the Ministry of Health—should take heed of this comment from the writer on the Service in Scotland: "The men who work it, however, are not, in general, working in a contented state." If medicine is to continue to attract into its ranks able men and women it is above all imperative that the terms and conditions of service should so evolve as to produce a profession which will do its work in a happy and contented frame of mind.

SERUM JAUNDICE

"Blood and plasma are potentially dangerous fluids unless prepared, stored, chosen, and used with extreme care." This statement was emphasized more than a year ago in these columns.[1] Blood and plasma are still being used in larger quantities than during the war and the need for "extreme care" has not grown less. Lehane and his colleagues[2] in a recent issue of the *Journal* discussed serum jaundice as one of the hazards of transfusion therapy. In the last few weeks three children have died after the administration of anti-measles serum, and the inquests on these cases, reported elsewhere in this issue, have been given prominence in the lay press.

It was in 1936 that a few cases of jaundice occurred among the recipients of two pools of serum from apparently normal adults given as a measles prophylactic[3] and in people inoculated with certain batches of yellow fever vaccine containing human serum.[4] The clinical picture in these patients was similar to that of "catarrhal jaundice," but because the period between the injection and the onset of symptoms was two to four times as long as the presumed incubation period of catarrhal jaundice the implications were not appreciated at first. Further investigation of the origin of the disease in both groups suggested that the supposedly normal serum used might contain an icterogenic agent. Although it was shown that the yellow fever virus itself was not responsible in the patients who had received the suspected vaccine, no proof of the source of the icterogenic factor was obtained at that time. Some changes were made in the process of preparation of yellow fever vaccine in 1937, but human serum was still used, because certain experiments indicated that it was necessary for growth of the virus and to maintain the stability of the virus in the vaccine. No more cases of jaundice of this kind were recognized until 1940 in Brazil, where many batches had been given previously over a number of years with no ill effects. Further large outbreaks of jaundice were reported in 1941–2 among the recipients of batches of yellow fever vaccine made in the U.S.A., and in 1942 in England. By this time improved technique made it possible to change over to a vaccine with an aqueous base, and no further cases are known to have occurred since 1943, when this type of vaccine was introduced.

Soon after the beginning of the recent war infective hepatitis (catarrhal jaundice) reached epidemic proportions in military and civilian groups as it had in previous wars. At the same time jaundice was affecting many of the men undergoing treatment at some of the military treatment centres for venereal disease. It was realized, too, that jaundice was also appearing in patients who had been transfused about 60 to 120 days previously. Usually the patients had received different batches of plasma or of whole blood and plasma, and there was no proof that the disease was artificially produced and not contracted by contact. About the same time two pools of plasma were collected from two small groups of apparently healthy young recruits recently recovered from mumps and were used to inoculate several hundred soldiers in the same camps to protect them from mumps. Some 60 days later cases of jaundice were noted among the inoculated personnel, and eventually at least 37% of them developed jaundice.[5] The investigations that followed incriminated only one of the two pools of plasma. There was no suggestive history of catarrhal jaundice among the donors, either before or after the time they had been bled. These results, together with the demonstration by Oliphant and others[6] in the U.S.A. that the disease produced by icterogenic yellow fever vaccine could be transmitted by injection of the patients' blood, and MacCallum and Bauer's experiment[7] showing that the pool of normal human serum incorporated in an icterogenic vaccine was itself icterogenic, made clear that the serum of certain normal individuals contained a transmissible agent which produced a clinical picture similar to that of catarrhal jaundice. Biopsy specimens of the liver from some of the patients showed that the pathological changes in the liver resembled those of infective hepatitis.

Then Spurling, Shone, and Vaughan[8] reviewed in this *Journal* their experience over the years 1940–5 at a large London blood transfusion centre. A disease considered

to be serum jaundice was found to have affected 7.3% of 1,054 recipients of pooled plasma. These were the years when infective hepatitis was prevalent in this country. Now Lehane and his colleagues have carried out a similar survey from October, 1945, to March, 1948, in the Liverpool area. Although the incidence of jaundice in the population was probably at pre-war levels and much lower than in the war years, the jaundice attack rate in recipients of large-pool plasma was 11.9%, and even in those receiving whole blood or small-pool plasma (not more than 10 donors) the rate appeared to be considerably higher than that in the community at large.

Attempts to reproduce either serum jaundice or catarrhal jaundice in experimental animals have been unsuccessful, and no *in vitro* diagnostic test is available; elucidation of the problem has therefore been difficult. Much of our knowledge has been obtained by experimental inoculation of human volunteers, with all its accompanying pitfalls. We still do not know whether these are two forms of the same disease process or not, but it is possible that there are several viruses or strains of viruses which have slightly different modes of action in their human host. In addition to several apparent differences in routes of infection and excretion between the agents causing infective hepatitis (catarrhal jaundice) and some of those responsible for so-called serum jaundice, there has been one important epidemiological difference—that of age incidence. Naturally occurring infective hepatitis has a maximum incidence in those aged 5–15 years. Occasional frank cases occur under 5 years of age, but even in nurseries it is usually the young teen-age nurses who contract the disease, while the children remain free. Over 15 years of age the attack rate in the civilian population usually falls gradually until 35 years, after which age the disease is uncommon even in groups of military personnel. By contrast, serum hepatitis has been very uncommon under the age of 5 and uncommon from 5 to 10, but it affects adults of all ages with more or less equal frequency, the attack rate varying from 15 to 50% in different outbreaks. Several cases of jaundice occurring two to four months after the transfusion of infants in the first few months of life have recently been reported in the U.S.A. and in England.[9,10] The source of the infection could not be determined. The possibility of the transfused material being responsible was inferred from the "incubation" period. Lehane and his colleague found only one case (aged 9 years) of jaundice (0.8%) among 127 children under 10 who were transfused with pooled plasma or plasma and blood, and there were no cases among 87 children who received blood alone. The attack rates by 10-year age groups from 10 to 70 were 5.7, 6.8, 7.1, 9.1, 9.3, and 8.1%, respectively.

It is well known that when infective hepatitis is epidemic there are large numbers of patients who have symptoms of the disease but do not become jaundiced. It has been inferred that at the same time there may be a number of individuals who have a symptomless infection during which the virus would be circulating in their blood. Transmission experiments in volunteers have failed to reveal any evidence that the patient recovered from infective hepatitis, or the one who develops chronic hepatitis, continues to carry the virus in the blood or excrete it in the faeces.[11,12] Similarly, Oliphant and others, MacCallum and Bauer, and Havens[13] have all failed to find any evidence of an icterogenic agent in the serum of cases of serum jaundice two months or more after their attack. In a follow-up of donors in Lehane's investigations only one could be traced who had had jaundice, and his illness occurred three months after he had been bled. Lehane and his colleagues conclude that at least 0.35% of donors are probably carriers of an icterogenic virus. These results all suggest that persons with symptomless infections are the chief danger, and in order to meet demands for plasma a few donors who have had jaundice more than a year ago have been used. In America, the Red Cross Blood Products Subcommittee suggested six months as the safe interval.

It has been recognized for about thirty years that convalescent measles serum may be injected into exposed contacts during the incubation period to prevent or decrease the severity of the attack. Since about 90% of the adult population in most countries have had measles, the modern tendency has been to use the readily available pooled adult plasma. Measles and its complications are responsible for much morbidity and mortality, particularly in children under 3 and in rheumatic, tuberculous, and bronchitic children of all ages. The value of this prophylactic procedure in such children has been proved without question. More recently, Cohn and his colleagues[14] at Boston have produced a gamma globulin fraction which represents about a twenty-five times concentration of serum. This fraction has been used on a large scale in the U.S.A. and is said to be superior prophylactically to adult serum. In addition, serum jaundice is said not to have occurred in the recipients of gamma globulin. Thus, though the age group attacked by measles appears to be relatively insusceptible to serum jaundice, it will be desirable to use gamma globulin instead of adult serum as soon as supplies are generally available in this country. Gamma globulin is expensive to prepare and some of the special equipment necessary is not yet readily obtainable; the production of adequate quantities, even if sufficient serum was available, is therefore no small problem.

The same gamma globulin fraction prepared from pooled adult serum appeared to reduce the attack rate

in adult and child contacts of infective hepatitis in the U.S.A. but was ineffective in serum jaundice. In one experiment the convalescent serum of a patient infected with a known strain of serum jaundice virus failed to neutralize that same virus. Treatment of either infective hepatitis or so-called serum hepatitis has, for the most part, been ineffective. The only treatment that has given any promise whatever has been the intravenous injection of protein hydrolysate. Since we cannot detect these viruses, inactivation is the main safeguard in order to avoid them. The icterogenic agents concerned pass through Seitz filters and are not inactivated by heating at 56°–60° C. for half an hour or by the usual bacteriostatic or bactericidal chemicals used for preserving sera, such as phenol, tricresol, or merthiolate. Recent work has shown that irradiation of serum or plasma with a particular unit of ultra-violet light under satisfactory conditions may be capable of inactivating any icterogenic or other virus present.[15] This procedure is being adopted, as equipment becomes available in the U.S.A., Canada, and England, as a routine treatment for pooled human serum or plasma which is to be used for transfusion or other therapy or prophylactically against certain infectious diseases.

REMUNERATION OF GENERAL PRACTITIONERS

A deputation from the British Medical Association, led by Dr. S. Wand, Chairman of the General Medical Services Committee, discussed with the officers of the Ministry of Health for more than three hours last Friday the evidence presented by the Ministry of what general practitioners in the National Health Service are now supposed to be earning. A further meeting with the Ministry will take place before, it is hoped, the Conference of Local Medical Committees to be held on October 27.

STAPHYLOCOCCAL TOXAEMIA

At Bundaberg in Australia in 1928, 12 children died after an injection of diphtheria prophylactic—a toxin-antitoxin mixture not containing antiseptic. This prophylactic had already been used on three different occasions without abnormal reaction. Three days later 21 children were inoculated, and within five to seven hours 16 became ill with high fever, vomiting, and diarrhoea. In the fatal cases the children developed cyanosis, convulsions, and unconsciousness, and died in 15 to 36 hours. A Commission[1] which was set up to inquire into the circumstances of this disaster reported briefly as follows: that the deaths were due to the injection of the diphtheria prophylactic; that the material contained no free diphtheria toxin; and that it *did contain* a culture of *Staph. aureus*. A similar staphylococcus was isolated from all the surviving children who developed abscesses at the site of injection. The cause of death was attributed to the toxaemia induced by a copious formation of toxin resulting from the growth of the staphylococcus. The Commission showed that in the conditions prevailing at Bundaberg very little toxin was produced *in vitro*, and so the toxin must have been formed *in vivo*.

In 1930 Kellaway and his colleagues[2] described a pharmacological study of the exotoxin of *Staph. aureus*. They injected agar-extracted toxin intravenously into young cats. After doses of more than 0.1 ml. per kg. the cats died rapidly, while doses of 0.04 ml. per kg. produced diarrhoea and weakness lasting 2–3 hours, followed by recovery. In cats dying in 2½–4 hours the earliest symptoms were dyspnoea, vomiting, and diarrhoea; these developed within 30 minutes and were accompanied by general weakness and ataxia. Later the animals became increasingly weak and collapsed, with convulsive movements; death followed respiratory failure. At post-mortem examination distension of the right side of the heart was observed and an empty left auricle and ventricle. Heart–lung preparations showed that there was constriction of the pulmonary vessels. When the lungs were replaced by an artificial pulmonary circulation it was found that the toxin had a direct toxic action on the heart: this was shown to be due to constriction of the coronary arteries.

Recently Olin and Lithander[3] have reported from Stockholm four cases similar to those at Bundaberg. Three children fell ill after the injection of measles convalescent serum: vomiting, diarrhoea, fever, and cyanosis rapidly developed, and two of the children died. The bottle of serum, which contained quinosol and formalin as antiseptics, had been used eight months previously without ill effect. The fourth case was that of a child on whom a Mantoux test had been performed, 1 mg. of tuberculin having been injected intracutaneously. Within four hours the child became ill, with vomiting, diarrhoea, and fever, and he died in 17 hours. From all four cases coagulase-positive staphylococci were isolated. Tests on rabbits showed a definite correlation between haemolysin titre, necrotic effect on the skin, and killing power. Burnet[4] in 1929 noted the same correlation in the Bundaberg strain and suggested, in fact, that the three effects were due to one toxin.

In cases such as these, in which the mortality rate is high and the onset of death rapid, early treatment is essential and the ominous nature of the symptoms should be widely appreciated. Fatal cases have followed diphtheria immunization, injection of measles prophylactic, and Mantoux testing—procedures common in this country. In Sweden one case, that following the Mantoux test, was treated with penicillin, but treatment was begun only within 1½ hours of the child's death. Prompt recognition of these symptoms after an injection would enable penicillin and staphylococcus antitoxin to be given at once. With early treatment there would be some hope of reducing the very high case mortality rate of a condition which, admittedly rare, might occur in the practice of any doctor.

REORGANIZATION OF THE MEDICAL SERVICES OF THE ARMED FORCES

BY

E. A. SMYTH, M.B., M.Ch.Orth., F.R.C.S.I.
Major, R.A.M.C.

I apologize for suggesting improvements in medical services that have weathered two great wars with honour, but I do so in the belief that a system of the type I describe might be more suitable in a future war and would make medicine in the armed Forces in peacetime more attractive than at present. I suggest that the medical services of the Royal Navy, Army, and R.A.F. should be preserved, as each Force has its particular problems, but that these services should be relieved of their responsibility for providing permanent hospitals. They would continue to administer preventive medicine but would retain control only of medical inspection rooms, field ambulances, casualty clearing stations, and similar mobile or semi-mobile units.

All permanent hospitals at home and abroad would be taken over by a new service to be known as the "National Health Defence Service." The director-general of this service (a civilian or an ex-Service chief) would be appointed by, and be responsible to, the Minister of Health. Under him would be three deputy director-generals appointed by the director-general of each of the three medical services. These deputies would be either retired officers or those still on the Active List and seconded for this duty.

The hospitals would be situated (1) in "safe" areas near large cities and (2) where there are normally large concentrations of Service men and women. In peacetime they would admit civilian as well as Service patients, but priority similar to that afforded seamen by the Seamen's Hospital Society would be given to Service personnel. In wartime these hospitals would be taken over as required by the Services, and they would accept air-raid casualties from neighbouring towns. The buildings would be constructed cheaply, but with adequate equipment, and would be capable of rapid expansion in time of war for training the staffs of base hospitals at home or overseas. During hostilities the command of base or permanent hospitals within the area of active operations would be handed over to the Service most concerned.

Staffing

National health defence hospitals in the United Kingdom would be staffed as follows:

House Officers.—Regular officers under training and newly qualified civil doctors serving under the same conditions as in civil hospitals.

Registrars and First Assistants.—Regular officers under training as specialists, and civil doctors serving under the same conditions as in civil hospitals.

Specialists.—Regular specialists on the Active List who are not required for the mobile units of the three Services and regular specialists who had elected to transfer to the "Home Only" list (to be described later) after fifteen years' service. There would also be part-time civil specialists.

Consultant Specialists.—Civilian specialists from the nearest centre who would visit their respective departments once a week. On the outbreak of war they would be given full duties as consultants or advisers.

The staffing of these hospitals abroad in peacetime would have to be carried out largely by Regulars.

Conditions of Service

Approximately one or two years after qualification officers would be recruited into one of the three Services as at present. During the first four years each would act as a general duty officer in any part of the world. At the end of this period those who wished to leave the Service, or who were not selected, would receive a gratuity. The others would be granted regular commissions. These officers would enter, partly by selection and partly by choice, one of the following three classes: (1) general and administrative officers; (2) specialists in preventive medicine; and (3) specialists in curative medicine. All would receive four to five years' training as follows:

General and Administrative Section.—(1) Three and a half years as house-physicians and house-surgeons in a national health defence hospital, partly abroad and partly at home. The aim of this instruction would be to make the officer a well-trained general practitioner. (2) A twelve-months apprenticeship in preventive medicine abroad. (3) A three-months course in the Service aspect of medical subjects at the corresponding medical college. (4) A six-months course at a naval, military, or Royal Air Force staff college.

Preventive Medicine Section.—(1) A one-and-a-half-years apprenticeship in a national health defence hospital abroad in the specialties related to preventive medicine—i.e., pathology, medicine, dermatology, and venereal disease. (2) A one-year apprenticeship in hygiene abroad. (3) A two-years apprenticeship in civil and Service preventive medicine at home, with facilities for taking a diploma of public health. (4) A three-months general course at a Service medical college. (5) A six-months course at a naval, military, or Royal Air Force staff college.

Curative Medicine Section.—(1) A four-years apprenticeship as a registrar in the officer's chosen specialty at a national defence hospital at home, with facilities for taking a higher degree or diploma. (2) A three-months course at a Service medical college.

Officers from the general and administrative and from the preventive medicine sections would then return for duty with their respective Service. Men and women in the curative medicine section would continue to work in national health defence hospitals at home or abroad, but a few would be required for semi-mobile establishments. Officers in the general and administrative section would gain experience in administrative posts and do clinical work in areas where the employment of specialists would be wasteful. Those in the preventive medicine section would be employed in their specialty or in administrative work.

On completion of fifteen years' service all regular officers could elect to transfer to a list called "Home Only." Posts would be guaranteed. Those who transferred to this list would be employed in the following ways:

General and Administrative Section.—As administrators in the national health defence service or in specially reserved posts in civil practice.

Preventive Medicine Section.—In administrative posts in the national health defence service, and certain posts in the civil health service would be reserved for such officers.

Specialists in Curative Medicine.—In permanent posts in their specialty in a national health defence hospital.

Officers transferred to the "Home Only" list would be able to continue in the national health defence service or a civil health service until the age of 60 or 65. On retirement their years towards pension would be assessed from the date of enlistment with the Services. They would be available for active service on the outbreak of war, and in periods of necessity other than war they could also be called on. This period of recall would not include more than one and a half year's foreign service.

Officers selected for high administrative posts at the end of fifteen years could be offered inducement to continue in the Services as long as required. The nursing services of the armed Forces would be brought into line with the system I have suggested for the doctors.

Advantages

In addition to answering most of the criticisms of the present system these proposals have other advantages. The total cost to the State of all medical services (civil, the suggested new defence service, and the medical services of the Royal Navy, Army, and R.A.F.) should be less than at present. In the first instance Service doctors would be employed in peacetime to full advantage, and would continue to be gainfully employed until the age of 60 or 65. Secondly, the waste caused by separate permanent hospitals for the three Services would disappear. Finally, the employment at small stations of well-trained medical officers of the general and administrative section instead of specialists would be more economical than

the present system, which requires a full complement of specialists in areas where their work is light.

The national health defence hospitals would not be an additional burden of expense to the State, as the number of civilian hospitals needed would be reduced. If war broke out a chain of hospitals capable of rapid expansion would be available in safe areas outside large cities. These national health defence hospitals would be centres of co-operation between Service and civilian doctors and between medical officers of the three Services. This liaison would lead to uniformity of organization, methods of treatment, and types of equipment. Possibly the medical services of the Forces would become merged into one at some future date.

Many civilian and Service doctors believe there is no necessity for Service hospitals in any form in the United Kingdom in peacetime. They consider that all naval, military, and R.A.F. patients could be treated in civil hospitals or if necessary in separate Service wards. This outlook is dangerous. Under such a plan all Service organization would rapidly fall into disuse and on the outbreak of war there would be no effective hospital system capable of rapid expansion to meet the demands of the Services at home or abroad.

My grateful thanks are due to many civilian and Service doctors for their advice, and especially to my commanding officer, Colonel Wm. C. McKinnon, for his willing and helpful criticisms. I am grateful to the Director-General, Army Medical Services, for permission to publish.

STREPTOMYCIN

Available on Prescription

The following notice has been issued by the Ministry of Health.

Scarcity of streptomycin in this country has hitherto imposed a strict control over distribution and limitation of its use to certain conditions. Production has now increased to such an extent as to enable streptomycin to be made generally available on prescription through the usual channels as from November 1, 1949. After November 1 the only administrative controls over this antibiotic which will be operative will be those imposed by the Therapeutic Substances Act, which concern its manufacture, and those under the Penicillin Act, which make its procurement subject to medical prescription.

Hitherto the use of streptomycin in this country has been mostly limited to a controlled study, in an institution, of its effects in certain categories of cases. The extension of these categories has been notified to the profession in press notices issued at intervals during the past two years. Though supplies will be adequate in future for domiciliary use, it is still important that the drug should be employed only in conditions, or to combat infections, in which its efficacy is known. This implies a knowledge of the susceptibility of the infected organism to the antibiotic as well as of the actual condition which it is proposed to treat. Unless this knowledge is possessed before the institution of treatment the reason for any apparent inefficacy of the antibiotic may be difficult to ascertain. An example of the apparently anomalous action of streptomycin is that, whereas it provides the only effective treatment for tuberculous meningitis, it has not been shown to have any specific value in the treatment of chronic pulmonary tuberculosis, both of which conditions are caused by an organism known to be sensitive to the action of the antibiotic. If, therefore, treatment is based on analogy and not on ascertained facts disappointment may be caused both to the practitioner and to the patient. The proper place for the experimental trial of this antibiotic in unusual conditions is the hospital, not the home.

Streptomycin has two main disadvantages. These are: (*a*) certain toxic effects which may be permanent; and (*b*) the evolution during treatment of strains of the infecting organisms which have developed a resistance to streptomycin. It has been thought that the substitution of dihydrostreptomycin for streptomycin itself would reduce the danger of the occurrence of toxic sequelae. The evidence at present suggests that, though the appearance of toxic effects may be somewhat delayed, dihydrostreptomycin may manifest them on its own account. It is therefore most important to employ adequate doses from the beginning of treatment, and in certain conditions it may be preferable to give larger doses than usual for a period not exceeding one week, as serious toxic effects do not appear to develop within that period. In any case, if the expected therapeutic response is not obtained in that time, reconsideration of the treatment is indicated.

No benefit has hitherto been recorded in the prophylactic administration of streptomycin with the object of preventing spread of infection following surgical intervention.

MEDICAL DEFENCE UNION

The annual report of the Medical Defence Union, which was presented to the general meeting of the Union on September 20, gives a synopsis of the many questions having a legal aspect which may confront the practitioner, and mentions some interesting cases in which the perversity of patients, the accident of circumstance, and sometimes the failure of the practitioner to take precautions resulted in difficulties. Of the cases passed to the Union's solicitors during the year, 69 in one form or another involved the issue of professional negligence. Of these 69 cases, 13 were fought out in court, where two were lost and 11 were won. In a further 16 cases it was thought necessary to make *ex gratia* payments in settlement of claims on the clear understanding that no admission of negligence was made; in 39 cases allegations of negligence were expressly withdrawn or abandoned in face of the knowledge of the interest of the Union in the matter and on the issue being formally challenged. Not a few accusations of negligence arise when an account is disputed by the patient.

Requests for Sterilization

It is mentioned that members are from time to time approached by patients with a request for sterilization. Counsel's opinion on this matter was first sought some years ago, but owing to the time which has elapsed since then, and the changes in medical thought and social conscience, it was felt that a new opinion should be taken. The opinion is that sterilization on eugenic grounds alone is illegal, but that it is not so if there are valid therapeutic reasons—in other words, if there are conditions which may imperil health or life if sterilization is not performed. This places sterilization on the same basis as abortion and calls for similar safeguards (including a second opinion and the written consent of the patient) on the part of the practitioner.

The Practitioner and Ancillary Examinations

In his presidential address at the annual meeting Mr. St. J. D. Buxton touched on the question of the responsibility of the practitioner concerning ancillary examinations. He pointed out that the patient knew little or nothing about the work of specialists, and if a practitioner acted on an *x*-ray, pathological, or other report which happened to be erroneous, though given in good faith, he might be charged with negligence, with the other doctor as co-defendant. Hence it was of the utmost importance that consultation with those carrying out ancillary examinations should be made, at least whenever there was doubt, for the sake of both patient and doctor.

He also mentioned that members frequently ask advice regarding inquests, and during the year legal representation had been afforded in 20 instances. Practitioners were sometimes accused during inquest proceedings of negligence in the treatment of the deceased, but such allegations had been successfully refuted. Action had also been taken by the Union to ensure that practitioners received their statutory fees for evidence of medical fact or opinion given at inquests.

Mr. Buxton intimated his desire, having been re-elected president for several years, to give place to another member. After placing on record its sense of the value of Mr. Buxton's exceptional services, the meeting proceeded to elect as the new president of the Union Mr. Ivor Black, F.R.C.S.

In view of the upward trend of all costs, the meeting agreed to a recommendation of council to increase the subscription rate from January 1, 1950, to £2 per annum except for the first

three years of membership of those elected within three years of registration, for whom the subscription would remain at £1. It was explained that during the last two years the total expenditure had exceeded the income from all sources by £20,000. Last year the subscription income was over £30,000, and the law expenses and indemnity claims alone cost over £35,000. It appeared to the council improvident to continue to deplete the Union's invested funds.

TREATMENT OF CEREBRAL PALSY

DR. EARL CARLSON'S ADDRESS

A meeting of the British Council for the Welfare of Spastics was held at the Royal Society of Medicine on September 21 for an address by Dr. EARL R. CARLSON, of Philadelphia Hospital, New York, on the treatment of cerebral palsy. The chair was taken by Professor Alan Moncrieff.

Dr. Earl Carlson said that cerebral palsy was a disturbance of musculature almost as prevalent as poliomyelitis. In most cases the cause was injury to the brain during birth or the faulty development of brain cells; occasional causes were toxic factors, encephalitis or meningitis, and, in certain conditions, disturbances of the Rh blood factor. In cases with choreoathetosis and spasticity there had always been dispute about the location of the cerebral lesions, and especially whether the disturbances in muscular movements resulted from damage to the basal ganglia. There was a group of patients with choreoathetosis and various degrees of spasticity whose response in certain situations, and to treatment, was such as to make one hesitate to place the lesion chiefly in the basal ganglia; in these cases one might well speculate upon damage to the motor or sensory cortex.

The treatment of cerebral palsy was an educational as well as a medical problem. The tremors, writhing motions, and grimaces were so intimately tied up with the thought processes that it was difficult to regard these movements as something apart from feelings. Excitement and lack of concentration aggravated the condition; with tranquillity and peace of mind the motor activity became much more purposeful. Cases of cerebral palsy suffered not only from unruly muscles but also from disorganized thoughts and emotions. The extent of mental disability bore no relation to the amount of motor handicap. A child with serious motor involvement might have better intelligence than one with a slight physical impediment.

The majority of speech disturbances formed part of the general motor disturbance. Here again the extent of the speech defect bore no relationship to the degree of mental impairment. In one group a child with the lowest intelligence quotient was one of the best speakers and singers. The outstanding characteristics of the defective speech were lack of smooth rhythm, poor articulation, absence of subtle shadings and nuances, and an accompaniment of inappropriate contortions. Speech was an intricate muscular process, and its disturbance was so closely linked with the general spastic-athetoid condition that not much improvement could be hoped for until the child learned to inhibit the excessive sensory stimuli which were irrelevant to what he was doing. He resembled a public speaker trying to overcome stage fright. If he was too conscious of his audience he would have difficulty, but when he directed his thoughts to the topic of his address his delivery improved. Similarly the child who could forget himself and concentrate on what he was saying had less difficulty in speech.

Physiotherapy, Surgery, and Drugs

Physiotherapy must be adapted to the individual case and related to the clinical findings. In spastic conditions there was usually a powerful simultaneous contraction of both extensors and flexors, and the limb became rigid. Treatment was directed to overcoming this condition by teaching the spastic child to relax one set of muscles as the opposing muscle group was brought into action. The child with the scissors gait, for example, was taught to spread his legs apart after he had relaxed the muscles that kept them crossed. In treating athetoid conditions relaxation was of primary importance. Training should be directed towards keeping the patient occupied and at the same time to "keeping his mind off his muscles." This could be done by directing his attention to the purpose of the act rather than to the muscles which performed it. Occupational therapy was a valuable adjunct in treating all types of cerebral palsy. Water treatment was often conducive to relaxation, but was not as effective as in poliomyelitis.

Visual training was important. The child with cerebral palsy had difficulty in correlating muscular activity and perception. He tried to look in too many directions at once, and when there was difficulty in correlation muscular tension developed. The origin of many "fears" might be traced not to an unpleasant experience and its associations but to a muscular tension which developed because of lack of integration between perception and motor activity.

The physiotherapist who treated spastics should be a person with a temperament and personality conducive to relaxation. The exercises should be slow, co-ordinated, rhythmic movements, beginning with the major groups of muscles. In younger children it was often necessary to assist them passively until they were able to carry out the movements by themselves.

Surgery often helped a programme of muscle training; it was more effective in spastic than in athetoid conditions. Lengthening tendons, arthrodesis, tendon transplantation, obturator neurectomy, and neurectomy of the nerves to the gastrocnemius muscle were sometimes helpful, but must be followed by a course of exercises. On the whole, little was accomplished for the athetoid case by peripheral operations on nerves and muscles. Posterior root section and operations of the Stoeffel type were contraindicated, and stabilization of the ankle or tenotomy of the Achilles tendon when much athetosis was present was seldom helpful. In severe cases of athetosis involving one arm, resection of the anterior portion of the corresponding motor cortex had been successful in some cases. Section of the extrapyramidal pathways in the spine had yielded favourable results in some of the most distressing cases of athetosis. The use of braces and splints was more helpful in spastic conditions; in athetosis, except in mild cases, they usually aggravated the condition.

Drug therapy had not been as effective as popular literature led them to believe. Sedatives should not be used except in convulsive disorders, and then only to diminish the attacks without giving rise to drowsiness. Any drug which tended to depress mental activity made the patient less responsive to treatment. A cup of coffee would often do more than a sedative. Alcohol in many cases had some effect in controlling athetosis and spasticity. In a film which Dr. Carlson showed subsequently a patient who had been unable to bring a full glass of water to her lips without spilling the contents had no difficulty whatever after consuming 2 oz. (60 ml.) of whisky.

Education and Vocation

The mental growth brought about through education was the most important factor in amelioration. When a cerebral palsied child was placed in a school and became occupied, an improvement in muscular control was often seen without special emphasis being placed on muscle training itself. Parents who delayed academic training until the child acquired better control of his hands or speech were surprised at the rapid improvement in muscle control which followed when the child was finally allowed to go to school.

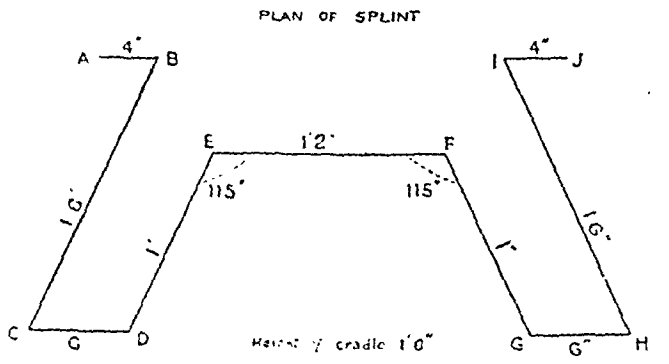
Every educable cerebral palsied person should have the right to an education irrespective of the extent of the affliction. Special schools should be provided for those too seriously handicapped to fit in a normal school environment. The schools should be equipped to give physical and occupational therapy, speech training, and other remedial activities.

All the cerebral palsied, of course, could not benefit to the same degree from an educational programme. The severely and hopelessly handicapped must no doubt be admitted to institutions, though they should not be treated as idiots. Others whose physical handicap was less severe, although their mentality prevented them from benefiting from education above the lower grades, must be guided into routine occupations. Those

who had good intelligence should not be barred from obtaining as much educational training as they could benefit from, even though their physical handicaps were of such a nature as to close many vocational avenues.

The solution of the vocational problem was dependent upon many factors. One of the most important was the patient's attitude to his own handicap. He must be prevented from developing a morbid attitude. There was almost always a way of circumventing the handicap. Dr. Carlson mentioned one or two cases of surprising achievement. One girl had won a college degree and made a career for herself as a teacher of the blind, thus freeing herself from the sense of being an object of curiosity to her pupils. One severely handicapped man, whose speech was then wholly unintelligible, had formerly earned his living in New York by selling newspapers, but he had educated himself, taken the degrees of M.A. and Ph.D., and was now teaching in a school for the cerebral palsied.

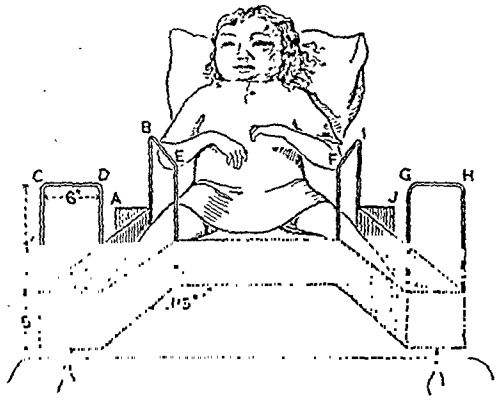
Mr. M. D. BOSWORTH SMITH said that Dr. Carlson himself was the most noteworthy living example of triumph over handicap as the result of will power and concentration, intellectual and moral. He added that it was believed there were 10,000 children under the age of 16 in this country suffering from cerebral palsy of various types. It was the aim of the British Council for the Welfare of Spastics to do what it could to encourage proper treatment by the establishment of special schools and clinics and the organization of research, but only the fringe of a vast subject had so far been touched in this country.



Professor ALAN MONCRIEFF said that on his computation, on the basis of American experience, the number of children afflicted in England and Wales should be 28,000, not 10,000 as Mr. Bosworth Smith had suggested. If the latter figure was right, we had for once the advantage of being on the right side of the account so far as America was concerned.

Preparations and Appliances

ANTI-EXTERNAL ROTATION ABDUCTION SPLINT AND BED CRADLE



Mr. E. K. MCLEAN, Medical Superintendent, Southlands Hospital, Shoreham, writes: After the insertion of a 'Smith-Petersen pin for fractures of the femoral neck maintenance of the correct position in the patient is of great importance. External rotation of the thigh may lever the pin out of position, as may forcible adduction of the thighs. Flexion and extension movements of hip-, knee-, and ankle-joints are, however, to be encouraged. The problem is often met by making the patient wear slippers with wooden supports glued to the soles. These appliances, however, limit movements, are uncomfortable, and may produce pressure sores unless carefully supervised.

The splint described below has been used very successfully at Southlands Hospital as a combined abduction anti-external rotation splint and bed cradle. It can be made up easily and

cheaply by the hospital engineers, as it is of very simple construction.

The instrument works on the same principle as the old-fashioned "stocks," but instead of the feet being fixed in apertures each leg lies in a padded gutter (cf. B,C,D,E and F,G,H,I). The framework of the gutters is made of 5/16-in. (0.8-cm.) bright mild steel rod. The walls of the gutters are covered with pillow ticking and padding of tow and cotton-

wool covered with old linen. The height of the walls is 6 in. (15 cm.) and the width of the gutters 6 in. Loops of steel rod join B to E, C to D, F to I, and G to H. These loops project upwards from the gutters for one foot so that the instrument may be used as a bed cradle. The two gutters are joined by a flat padded continuation of the medial gutter walls (E,F). There are also laterally reflected 4-in. (10-cm.) phalanges at A,B and I,J. These transverse phalanges and connecting wall prevent the patient from pulling a leg out of the gutter and thrusting it back on one or other side. The instrument does not prevent flexion and extension of hips, knees, and ankles. It does, however, prevent adduction or external rotation of the thighs.

At first it was found difficult to keep the padding on the splint clean. This difficulty is obviated by covering the splint with domette bandages. These should be wound so that the overlapping edges are away from the patient, as this prevents fraying.

The patient's comfort is increased by placing in each gutter a soft pillow made from a length of 6-in.-wide plaster stockinet lined with a strip of cotton-wool ½ in. (1.25 cm.) thick. A pillow of body-width plaster stockinet and cotton-wool about 2 in. (5 cm.) thick placed across the bed under the patient's knees prevents their hyperextension. Tapes are attached to the splint base at A, C, H, and J, so that the instrument can be tethered to the end and sides of the patient's bed. The employment of this splint has improved the percentage of recoveries in good position.

I have to thank Miss K. C. Savin, the charge physiotherapist, Mr. T. E. G. Sayer, chief hospital engineer, and Mr. H. Gander, assistant engineer, for much valuable help.

A cine-micrographic film library has been established by the Royal Microscopical Society for scientific films within the range of the society's activities. Hitherto many excellent films made in academic research institutions have not been accessible for educational purposes. It is hoped that the existence of this new library will facilitate distribution to universities, technical schools, and other scientific bodies. The collection is at present not very large, but it may claim to be representative. It contains films from the Pasteur Institute, Paris, by J. Comandon and de Fonbrune, on mitosis in *Triton* erythroblasts and in *Acanthamoeba*; films on micromanipulation; on spermatogenesis in the grasshopper, by K. Michel, of Jena; on the shape and motility of bacteria, by A. Pijper; and also films on the cultivation of living tissues, by R. G. Canti and his collaborators, and on tissue-cultures under the phase-contrast microscope. These films are available for hire on application to the Assistant Secretary, Royal Microscopical Society, B.M.A. House, Tavistock Square, London, W.C.1. The fees charged are 7s. 6d. for each 400-ft. reel when it is returned on the day following use: 1s. in addition for each subsequent day that the films are retained. The basic charge is reduced to 6s. for Fellows of the Royal Microscopical Society.

WHERE OTHERS FAIL . . .

Aureomycin Hydrochloride

AUREOMYCIN HYDROCHLORIDE *Lederle* gives promise of being one of the most versatile antibiotics yet discovered. It is a potent antibiotic against many Gram-negative and Gram-positive organisms and against primary atypical pneumonia. AUREOMYCIN has been found useful in the control of infections caused by penicillin-resistant Gram-positive cocci (especially staphylococci), and infections caused by coli-aerogenes bacteria. It is also highly specific against rickettsial infections. AUREOMYCIN has been used successfully against infections that have become resistant to penicillin, streptomycin, or sulphonamides, and in patients who exhibit severe and uncontrollable sensitivity to these latter drugs.

ADVANTAGES

Aureomycin exhibits the following advantages:—Essentially non-toxic (excepting allergy) . . . Unlikely to produce fastness in pathogenic organisms . . . Effective against many organisms previously insusceptible to chemo-therapy . . . Available in oral . . . and topical ophthalmic dosage forms.

CAPSULES: Vials of 16 capsules each containing 250 mg.
OPHTHALMIC: Vials of 25 mg. with dropper assembly; solution prepared by adding 5 cc. of distilled water.

Correspondence

The M.R.C.P.

SIR,—The Royal College of Physicians has accepted the report of the committee on the examination for the M.R.C.P., and this has now been open to criticisms. May I make some observations on the report and the criticisms?

The committee upholds the view that the examination should be "a test in general medicine, on a level higher than that required for qualification." That is to say, the subject matter is not materially different, but the standard is definitely higher. The committee returns to this later with the statement, "The examination is in general medicine. . . . The examiners are not entitled to condemn a candidate for lacking recondite knowledge." This is and always has been the accepted tradition of the College. Examiners are not bound by any regulations and may pursue for a reasonable distance paths leading outside these boundaries and occasionally may wander too far. But substantially a candidate stands or falls on his knowledge of the foundations of medicine and on his skill and experience, indeed one may say his common sense in applying these to the clinical examination of a patient.

Teachers have been known to advise candidates for the M.R.C.P. to cram up rare diseases, to memorize ephemeral theories, and to mug up articles in current numbers of the medical journals. No worse or more incorrect advice could be given. If followed, as undoubtedly happens, it fully justifies Professor J. McMichael's statement that study for examinations cramps and harasses excellent young men. But this is not and never has been the intention of the College or the standpoint of the examiners. The unfortunate candidate who follows this advice is riding for a fall. Properly conducted, "working for the membership" is extremely good training and calls for no detailed knowledge of specialized subjects. Even those who fail should have benefited by the experience. As the committee says, "The educational value of the clinical examination is far from negligible."

I pass to another matter. The report refers to differences of opinion about the purpose of the M.R.C.P. "On the one hand, membership of the College is widely regarded as the hallmark of the specialist, and the examination is looked on as a final test. . . . On the other hand, teaching hospitals more and more demand membership as a qualification for the post of registrar . . . and candidates are thus encouraged to take it early. No examination can fulfil two such different functions."

Now the M.R.C.P. has fulfilled both these functions satisfactorily—viz., as a guide for the appointment of a registrar and as a guide for the appointment of a hospital physician, but there is a difference in the manner and degree in which it does so. The applicant for a registrarship will probably have been qualified about three years and will have taken the M.R.C.P. some three or six months previously. Nobody expects him to be a finished physician. The electing body will view the M.R.C.P. exactly in the words of the committee's report—viz., that it signifies a "knowledge of general medicine which justifies further training as a consultant." The successful candidate then settles down to learn his trade. Some years later he applies for an appointment as hospital physician, for which the M.R.C.P. is essential. Applicants will not be expected to have passed the examination three or six months previously. Indeed a candidate who had only done so recently would be questioned closely as to why he had not taken it before: on the contrary he will be expected to have taken it when our registrar did so. Having satisfied itself that the candidate passed the M.R.C.P. at the proper time, the electing body then scrutinizes his record during the intervening years to decide whether or not he has fulfilled his early promise and can be accepted as a trained physician, either in general medicine or in some specialty. It is therefore not correct to say that "the examination is looked on as a *final* test" of a specialist: "initial" would be more accurate.

Here then is the answer or one answer to the question, Who is to decide at the end of such training that the possessor of the M.R.C.P. is or is not a failed specialist? The method does not always work fairly, but how many prospective hospital physicians would prefer the risk and anxiety of an examination at this stage, even if it led to a somewhat cheapened F.R.C.P.? Nor would it eliminate the inquiries of an electing board.

One more point. It has been suggested that the M.R.C.P. should scrap its present traditions and become an examination in special subjects. There is no cause for making any complete reconstruction of the examination either in this or other directions. The last paragraph of the committee's report states that it recognizes that "its proposals are for functional rather than structural change." It is right that this should be so. For the difficulties of the M.R.C.P. are due not to its failure but to its widespread success and sustained reputation. Nor is there any reason to believe that the present internal changes in the examination will lead to any alteration in its status.—I am, etc.,

London, W.1. HENRY TIDY.

Trends in Medical Education

SIR,—If the object of medical education were to train medical scientists and technicians, the plans for the reform of medical education outlined in the papers printed in the *British Medical Journal* of September 10 might produce good results. They will not produce good medical practitioners.

I have selected three points for comment. First, Professor Arnott's definition of medicine; second, his implication that the non-physical aspects of medicine are superstition and empiricism; and lastly his supposition that the scientific method is incapable of being applied to the art of medicine, the effective existence of which he denies. I have read his paper carefully, and hope I have not misunderstood him.

Is medicine an art? No one denies that it is, in part, a science. Quoting the *Concise Oxford Dictionary*, Professor Arnott defines medicine as a science and "an art only in so far as the term means human skill." On this assumption he outlines proposals for training scientific craftsmen. But is the art of medicine only a "craft"? One of the alternative definitions of an art given in the *C.O.D.* states that a fine art is one "in which mind and imagination are chiefly concerned." Surely the correct description of medicine is first a fine art, secondly a science, and thirdly a craft.

Abolishing "mind and imagination" from medicine (thence from medical education) necessarily means that we abolish individual and social psychology, and much else besides these, from medical education. Or perhaps it means admitting them as a concession to "superstition and empiricism," those persistent vulgar fractions that mar the mathematic exactitude of the pure sciences. The writer of your leading article deals neatly and with subtle humour with this travesty of medicine when he writes, "Though psychology has made but a shy appearance in these articles, it lurks in every corner." "Shy" is certainly the operative word in that sentence. Meanwhile psychology does not lurk in the corner of doctors' surgeries, but occupies more than 50% of their working time. Doctors do not have to deal with the "prevailing emotional pattern of man," but with persons who (it seems to me) will be extremely likely to be overlooked in this reformed medical education.

Lastly, Dr. Arnott implies that scientific method cannot be applied to the study of that part of medicine that is not science but superstition or empiricism. Hence I presume scientific method is inapplicable to clinical medicine, which is necessarily largely empirical. I should have supposed that the scientific method could be applied as conscientiously—if not as rigorously—to the art of medicine as to its science. Surely the difference lies not in method but in the relative proportions of measurable fact on the one hand and of clinical acumen (or insight) on the other. I affirm that the art of medicine can be practised scientifically every bit as successfully as its science can be practised artistically.

I hope these new proposals for the reform of medical education will be closely scrutinized. Doctors are not yet medical technicians nor scientific craftsmen, but they soon will be.—I am, etc.,

Lark Hill, Worcs. HOWARD E. COLLIER.

Hypnosis in Treatment

SIR,—Your correspondent Dr. K. M. Hay (September 17, p. 653) has expressed some misgivings about the therapeutic dangers of hypnosis on the basis of the theory described in his letter. I hasten to reply that those of us who employ hypnotherapy are not fully agreed that the dissociation theory can explain adequately the true nature of hypnosis. Dissociation does occur during hypnosis and is often facilitated by it, but this does not logically imply that hypnosis is merely a form of dissociation. For example, the variability and autonomy of the so-called dissociated symptoms seen during hypnosis cannot be accounted for by this theory any more than can the active and purposive participation of such symptoms in the total behaviour of the subject.

Changes in personality, as demonstrated by the Rorschach test, have been reported by various investigators. T. R. Sarbin (*Amer. J. Orthopsychiat.*, 1939, 9, 315) stated that there was an increase of "organizing energy" and the externally imposed *Aufgaben* circumscribed the response pattern to a greater extent than the self-imposed *Aufgaben*. Other personality changes have been reported when different moods have been produced under hypnosis, when anxiety is made to develop, or the subject is regressed. Such phenomena are not, as is suggested by Dr. Hay, indicative of a weakened personality but are merely changes of personality whilst in the hypnotic state. No evidence exists to suggest that these changes tend to become permanent.

Dr. Hay's conception of hypnosis as a mental assault by the hypnotist upon the subject is a false one cultivated by stage performers and charlatans. The true role of the operator in hypnotherapy is rather to introduce and guide the subject through the hypnotic experience, when the method becomes a truly valuable aid to the diagnosis and cure of mental illness.—I am, etc.,

London, W 14 NEVILLE MURRAY.

SIR,—Dr. K. M. Hay (September 17, p. 653) in discussing hypnosis as a form of treatment states that a hypnotized person is "depersonalized," that his intellectual faculties are suppressed, and then his mind is influenced on the feeling level by the hypnotist. In other words, the hypnotic subject is a passive automaton blindly responsive to the suggestions of the hypnotist. The hypnotized subject, as any medical man who practises this science will tell you, is by no means an automaton; a suggestion takes effect only if it is consistent with the balance of forces of the individual's strivings, and his understanding and elaboration of a suggestion are likewise determined by his own personality structure. The suggestion is really autosuggestion, just as there is no education but autoeducation, since it does not matter how much an individual is taught if he does not learn anything.

About a year ago I saw a girl with a cardiospasm that she had had for four years. The history revealed that it dated from the day her mother died. Under hypnosis she was told that she could not swallow the fact . . . that her mother died—that the mere thought of it stuck in her throat. It was through her intellectual faculties that understanding came and through the hypnotic power of suggestion that she was able to swallow.—I am, etc.,

London, W 1 A. P. MAGONET.

Distinction Awards

SIR,—Would any advantage be gained if we were to take a hand and grade administrators, superintendents, and the like? The waste of medical man-power might be reduced in this way. Although an advantage, it is not always essential for a superintendent to be a medical man. From time to time I have worked under three unqualified men who managed to unify the various requirements of the different hospital committees economically and with satisfaction to all concerned. One sees medical men in their prime superintending and inspecting hospitals, planning, etc., when they could be better employed working at medicine or surgery, in which subjects they have long been trained. The extra cost to the country must be considerable. Administrative work could well be left to older members. From long experience of the manner of it they might be glad to have a less strenuous and more regular and complacent mode of life during their declining years than they had when practising their profession.—I am, etc.,

London, W.1. G. H. COLT.

A New Neonatal Syndrome

SIR,—It was with much interest that we read the article of Mr. W. G. Mills on a new neonatal syndrome (August 27, p. 464), and we would like to record the following case seen recently and which appears to be identical with the eight cases in his article:

Male child, born June 9, 1949, by caesarean section on account of placenta praevia. At birth there was some respiratory distress, and nikethamide was injected into the umbilical cord.

On June 10 "bruising" of the left buttock and perineum was noticed.

On June 13, on the left buttock there was a network of small superficial vessels and some large deep ones. The movements of the left leg were weak, and there was slight oedema of the left foot, which was not being moved spontaneously.

On June 17 the condition of the buttock was subsiding, and it appeared as if thrombosis was taking place. There was still considerable weakness of extension of the left knee and dorsiflexion of the ankle. The general condition was always excellent, and the buttock became normal. At the time of writing the left leg is much improved following orthopaedic treatment in a plaster.

The condition of the buttock was almost identical in size and shape with that shown in Mr. Mills's photograph.

There was in this case the common factor of an umbilical cord injection, and it appears to us that the postulation of intra-arterial injection of a drug leading to thrombosis is the probable aetiological factor. A puzzling feature of the condition is that it has only recently been described although many thousands of injections into the cord must have been given, with the risk of intra-arterial injection. It would be interesting to know if the condition has occurred with lobeline alone. If nikethamide is the only drug concerned, has its chemical formula been changed recently?—We are, etc.,

CRYSTAL BATES.
Nottingham. A. P. M. PAGE.

Transfusion in Domiciliary Midwifery

SIR,—I have read with interest the controversy arising out of the letter of Dr. C. T. H. Whiteside (June 4, p. 1005) on the use of dried plasma in retained placenta. The following questions arise: (1) What is the maximum time during which a placenta may be left in the womb? (2) In a case of retained placenta with profound shock, what would be the ideal procedure to adopt—remove the placenta and then treat the patient for shock, or the reverse? (3) Which is the ideal fluid for intravenous transfusion in such cases—whole blood, blood plasma, gelatin solution, or saline with glucose? (4) What is the best anaesthetic to use for removing an adherent placenta?

I am in agreement with the opening sentence of Dr. H. A. Logan's letter (July 23, p. 232) that "in these days of synthetic medicine, diplomas, etc., it is refreshing to read some of the facts of life as expressed by those capable of using their powers of observation and confirming them with experience." Having done 22 years of midwifery as domiciliary practice, and not possessing anything better to transfuse than normal saline with glucose for an emergency, my working procedure in cases of retained placenta has been as follows. If I am on the spot when the second stage of labour is over and the placenta does not deliver itself in one hour, I remove it under soluble thiopentone. If, however, the retention is attended with more bleeding than I feel happy about, the period of waiting is less, depending on the amount of blood lost and the contractility of the uterus.

The difficult problem is the woman about whom a call is sent after the placenta has failed to deliver, and who is therefore seen in varying degrees of shock or collapse. I can look back on eight such

cases, the last of which proved fatal. She was a third para in normal health, despite so much malaria in this Protectorate. As a primipara her confinement took place in a normal way in my surgery. The second labour was so uneventful that no help was taken. Her third delivery was at 1 p.m. on July 17, 1949. At 3.45 p.m. the placenta had not delivered, though the attending African qualified midwife had made some attempts to deliver it. I was therefore sent for, and, the place being 20 miles (32 km.) away, I reached there at 5 p.m. No pulse could be felt at the wrist. She was restless, fully conscious, and extremely anxious about herself. She had been in labour for the best part of three days; and "after much suffering" she had brought forth the baby. Much blood had been lost, but her condition was one of "obstetric shock" from retained placenta and attempts made for its removal. The uterus was alternately contracting and relaxing. The following injections were given: (1) intravenous ergometrine; (2) adrenal cortex; (3) later, coramine; (4) intravenous saline with glucose, 1 pint (570 ml.).

At 5.30 p.m. the pulse could be counted at the wrist, and the uterus was well contracted. At 5.50 the uterus began to relax and bleeding started once again. At 6 the pulse was flickering. A quick decision had to be made. With a minimum of ether given by the open method by the assistant I used a half-elbow-length rubber glove and delivered the placenta. The placenta had been firmly adherent in one part of it; and it was some satisfaction to know that it would never have delivered itself. When I withdrew the hand there was hardly a pulse at the wrist. At 6.30 the lady died.

In a paper read at a medical conference held in Nairobi in February, 1949, on domiciliary midwifery practice in Uganda I made the following three important points about a retained placenta: (1) Credé's method, as taught, learnt, and practised in many places is attended with much danger; (2) it is wise to restore the shocked condition of the patient before doing manual removal; and (3) wiser still to use an anaesthetic for manual removal.

I wish to make another point. Those urgent cases in which manual removal without an anaesthetic is done, and succeeds without killing the patient, are the ones in which atonic retention of the afterbirth with a smart haemorrhage is the predominant factor. There has been no time in such cases for shock to supervene, for the simple reason that before this event happened the woman died of haemorrhage, or some bold person timely extracted the placenta without anaesthetic and saved a life. In one of my cases a lay, elderly woman did this heroic act before my arrival; I am not sure if she had washed her hands for the operation. The patient lived.—I am, etc.,

Iganga, Uganda. P. S. SANADE.

Poliomyelitis

SIR,—Now that it is the poliomyelitis season in this country I thought it would be of interest to describe my experiences in Ceylon during June, July, and August last year.

I was the medical officer to R.A.F. station, Negombo, which contained a total European population of about 750, including families. The station was 20 miles (32 km.) from Colombo and situated in a coconut plantation.

During this period several cases of paralytic poliomyelitis were admitted to B.M.H. Colombo from Army units in and around Colombo. Colombo was put out of bounds to our personnel, except on important duty.

At Negombo I saw a high proportion of cases of pyrexia in the younger Service personnel and children at this time. The clinical picture was as follows. The patient complained of headache, backache, slight diarrhoea, and a general feeling of weakness. The headache was severe, but not unbearable as in typhoid, and the weakness more than would be expected for the temperature, which was not usually high in spite of the climate. On examination, the physical signs were not convincing. Nystagmus was not found, but a doubtful neck rigidity was common. Most cases showed photophobia.

All patients were kept under observation in bed and not allowed up until their pyrexia had settled for at least 48 hours, provided that they were also symptom-free.

As far as I can remember I sent at least three refractory patients to B.M.H. Colombo, all of whom had a raised protein in the C.S.F. and all of whom settled eventually without paralyses.

Unfortunately, I myself developed headache, backache, and slight diarrhoea, and it was natural to conclude that it was psychological in origin; however, I retired to bed and stayed there. The feeling of weakness was most marked, especially in the legs, and somehow my mind seemed dull; but interest in poliomyelitis was sufficient for me to go right through the numbers of the *British Medical Journal* covering the 1947 epidemic in England. About five nights after the onset I woke up with the most terrific pain I have ever experienced, in my left shoulder. It was impossible to localize it exactly, and I could not relieve it by movement or position. It was so bad that I resorted to walking about the room, although I knew it was wrong. Morphine ¼ gr. (16 mg.) had no effect, and I slept after a further half grain. The next morning the pain had gone, except when I moved the shoulder. It took about ten days to regain full painless movement, and about a month later my supraspinatus and infraspinatus had wasted completely on the left side. There has been no recovery in these muscles, and apart from slight weakness I do not notice any limitation of function.

This letter has been written from memory, and the lack of detail is regretted, but it is felt that the majority of my cases were non-paralytic poliomyelitis.

The measures taken to restrict the disease were simply to tighten up on camp hygiene and especially fly control. Where there was a case in a family the parents were asked to restrict mixing with other families, but few parents were told the possible nature of the disease. It was felt that the disease was obviously so widespread that rest and observation of all fevers were more important than rigorous restrictive measures which would only cause unnecessary panic.—I am, etc.,

Ashford, Middlesex. N. G. NICHOLSON.

Poliomyelitis Vaccination

SIR,—As a mere medical student I hesitate to write this letter, and hope that in doing so I am not simply revealing a lack of fundamental knowledge.

I am at a loss to understand why the lead given not so long ago by Jenner and Pasteur in the modification or attenuation of a virus, so that it may be used for vaccination purposes, has not been followed in the case of other virus diseases, notably poliomyelitis. Surely did not Pasteur attenuate the rabies virus by drying the cord of animals suffering from the disease, having first elevated the virulence to the maximum possible level, and by injecting such dried cords of gradually increasing virulence so produce immunity? Could not a similar process be utilized in producing poliomyelitis immunity, which if successful, and if employed on the scale now used against smallpox, would remove this scourge from our midst?—I am, etc.,

Hatch End, Middlesex. M. H. F. JOHNSON.

Gravitational Ulcers of the Leg

SIR,—The recent correspondence following Dr. S. T. Anning's valuable article (August 27, p. 458) prompts me to mention one point in connexion with chronic or recurrent gravitational ulcers which has received little attention. It is that these patients commonly have a partial ankylosis of the ankle-joint, particularly if the ulcers are in the region of the ankle. This occurs so frequently that it is uncommon to find a full range of movement of the joint in patients who have such an ulcer of any chronicity. The ankylosis probably results from a number of factors. The ankle may be held rigid to avoid pain in the acute stages, or sometimes a patient is kept in bed for long periods with the leg held relatively immobile. The chronic oedema may play a part, and finally the wearing of paste bandages immobilizes the ankle-joint, often for many months.

The main cause of gravitational ulcers is generally suggested to be the devitalization of the skin by the chronic venous insufficiency and subsequent oedema. Ankylosis of the ankle obviously impairs the circulation, and the aid to venous return from muscular contraction is diminished. It is therefore apparent that such an ankylosis will augment the essential conditions responsible for the ulceration.

In many cases this ankylosis can be avoided by suitable foot and ankle exercises, preferably taught, and in some cases supervised, by a physiotherapist. Obviously, common sense is required in avoiding friction of the ulcer against bandages, etc., and in the initial stages the exercises should not be vigorous. With patients lying in bed regular exercises may also play a part in improving the circulation, and so accelerate healing. Paste and supportive bandages have a very important place in the treatment of gravitational ulcers and are used extensively. However, it must be weighed against the undoubted value of these measures that a degree of ankylosis with its attendant disadvantages will be more likely to occur following their prolonged use.—I am, etc.,

Bristol, 8. ROBERT P. WARIN.

Essential Hypertension in Pregnancy

SIR,—Professor J. Trueta's misrepresentation of my view (September 17, p. 650) is due either to a misapprehension or to other causes. He attributes to me the opinion that anuria "is not the result of a decreased intrarenal blood flow, but on the contrary that it is due to an increased blood flow to the renal medulla, which maintains the 'obstruction' of the uriniferous tubules"—as though I supposed an increased blood flow to and through the medulla is primary. Had Professor Trueta read my paper on eclampsia and its lesion (*J. Obstet. Gynaec. Brit. Emp.*, 1929, **36**, 341)—not mentioned in the 16 pages of the bibliography of his book—he would have found that I hold a very different picture.—I am, etc.,

Rugby. R. H. PARAMORE.

Parturition after Pneumonectomy

SIR,—As we cannot find in the literature any other case of a woman going to full term and parturition after a total pneumonectomy, we thought that it may be worth while to have the following case on record.

The patient is a 23-year-old primipara in good general condition (weight 8 st. 2 lb.—51.3 kg.). In 1942 Mr. T. Holmes Sellors performed a left pneumonectomy for gross bronchiectasis. In August, 1948, the patient became pregnant, and apart from slight oedema of the feet at the end of the day the pregnancy was uneventful. She went into labour in the early hours of May 3, 1949; the cervix was fully dilated by the evening of the 5th, but, as the patient was unable to push, medical aid was sought. She was delivered under chloroform anaesthesia by a high forceps manœuvre, preceded by an episiotomy. The episiotomy was repaired immediately after delivery. The child, a male weighing 6 lb. 3 oz. (2.8 kg.), was very shocked at first but recovered quickly on clearing the air passages.

—We are, etc.,

Colchester. F. KELLERMAN.
R. SAUVAN SMITH.

Memorial to Charles John Bond

SIR,—In the letter from Dr. Joan B. Walker and Mr. N. I. Spriggs (September 17, p. 655) referring to the fund which is being raised in Leicester to provide a memorial to the late Mr. C. J. Bond no reference is made to what was undoubtedly one of his great interests in the later years of his life—the question of voluntary euthanasia. He took a leading part in the formation of the Voluntary Euthanasia Legalization Society, and was the first chairman of its executive committee, a position he held until his death. It was at his personal invitation that the late Lord Moynihan became the first president of the new society, and doubtless it was largely due to the great prestige attaching to Bond's and Moynihan's names that the society made the rapid progress it did in securing the adherence and support of so many other distinguished members of the medical profession.

No review of Bond's life and work would be complete which did not include a reference to this aspect, and it is possible that in the years to come the great part he played in the initiation of this reform will be what he will be chiefly remembered and honoured for.—I am, etc.,

Leicester. C. KILLICK MILLARD,
Honorary Secretary,
Voluntary Euthanasia Legalization Society.

Old Age

SIR,—With increase in the numbers of those who have grown old, there arises the question, Can anything be done about it? If the majority of these had grown wiser, and kinder, and less selfish, one would not mind so much. But so many apparently live only for themselves. Daughters, and even sons, are kept at home to minister to the old people's wants, and these offspring are often prevented from marrying. I wonder, do they ever ask themselves, "What use am I in the world?"

The resources of the public, or private persons, have often to be expended on them; they take up the time and labour of many; they consume food, and occupy space that is badly needed for the younger. Why encumber they the ground? Segregation may be one remedy, or, more brutally, they might be induced to agree to voluntary euthanasia. But I doubt—even if it were allowed—that many would agree to this. What, Sir, is your suggestion?—I am, etc.,

Portsmouth. J. RUSHWORTH LUND.

Syringes

SIR,—I regret that my letter on the advantages of the Luer syringe fitting (August 13, p. 387) has led to a little misunderstanding. The type of fitting which I have found so useful in ophthalmic surgery (as it enables the injection to be made with one hand whilst withdrawing the needle, and without any risk of leakage) is the Luer-Lok fitting. After correspondence, I find that this is not yet available in this country, though it may become available in the next year or so. I hope that the production of this type of bayonet-joint fitting for hypodermic syringes will be accelerated, as it has great advantages for ophthalmic surgery and is even less likely to be obtainable from America now than it was.—I am, etc.,

Leeds, 1. JOHN FOSTER.

Local Analgesia

SIR,—In the *Journal* of July 16 (p. 139) there appears a review of the book *A Surgeon's Guide to Local Anaesthesia*. But why, oh why, do you have it reviewed by a specialist anaesthetist? The result is just what one would expect—namely, a half-hearted, brief, non-committal statement which does scant justice to the book. It may interest your readers to learn that this book has now reached its third edition, though the two previous editions appeared in Australia only, where they were issued by the author in typescript form owing to wartime difficulty in publishing. The volume is intended to be a guide not only for the practising surgeon but for all who have perforce to do operative work where trained assistance is not available, perhaps in villages far in the country, and who want to learn safe methods that will work and will not fail.

I may say that I am writing this letter because to-day I was proposing to perform an operation for haemorrhoids using caudal analgesia, but having read Mr. C. E. Corlette's strictures upon this somewhat dangerous method of local analgesia I decided to employ the ordinary infiltration method around the anal canal, using 1% procaine with adrenaline solution, 2½ minims to the ounce (0.53 ml. per 100 ml.), and all went well. The point that Mr. Corlette brings out in his book is that the infiltration method is a safe method, whereas the caudal injection is unsafe; it has led to deaths, as can be found in the literature if one takes the trouble to look it up. It is highly probable that a professional anaesthetist does not look with any favour upon a book which shows surgeons how to perform operations safely and reliably, and without troubling the general anaesthetist at all.

The main theme of the book is the author's unique premedication system, which puts the patient in a state of quiet relaxation, physically and mentally, and this enables operations to be performed without producing any mental or nervous strain. The patient either dozes off to sleep, or remains quiet and calm but awake. I have used his method in hundreds of cases, and with great success. Altogether the book is the most complete practical guide that exists at the present time, and the

Now from 1 injection of **PROLOPEN**

... high initial penicillin blood level

... prolonged penicillin activity

Newest addition to the new range of Glaxo penicillin preparations, PROLOPEN is a suspension of crystalline sodium penicillin G and procaine penicillin G in arachis oil with aluminium stearate. A 1 cc. injection of Prolopen provides both an early, powerful penicillin action, rising to a peak level of 1.0 to 2.0 units per cc., and a *sustained* effect lasting 24 hours or more.

This combined action of Prolopen is particularly valuable when treating conditions in which more resistant organisms are implicated (staphylococci, for instance) — organisms which cannot always be adequately countered by an oily injection of procaine penicillin alone.

Available in 10 cc. vials — GLAXO PROLOPEN

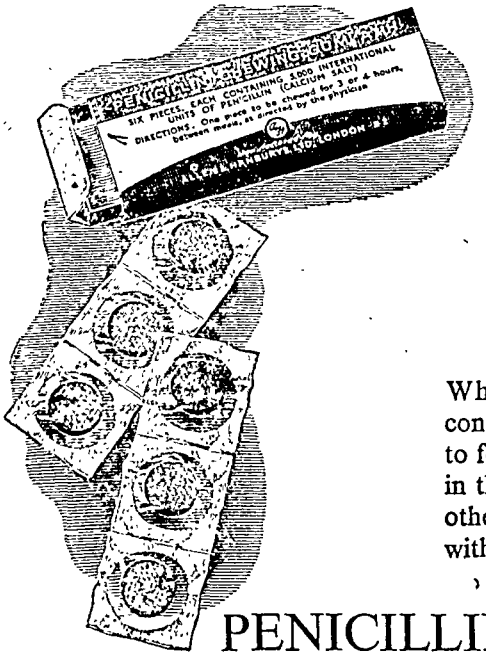
GLAXO PENICILLIN PRICES REDUCED as from Monday, October 3.

... now two

penicillin ointments

The purest form of penicillin—Crystalline Penicillin G—has been incorporated at high potency in the two new ointments introduced by Glaxo Laboratories.

Moreover, a special base has been developed which secures maximum stability of the penicillin content.



CRYSTALLINE PENICILLIN G OINTMENT *Glaxo*

Contains 2,000 units of penicillin per gram—this increased potency facilitating short-term, intensive therapy. The ointment is appropriately employed for all local infections caused by penicillin-sensitive bacteria. *In ½-oz. tubes*

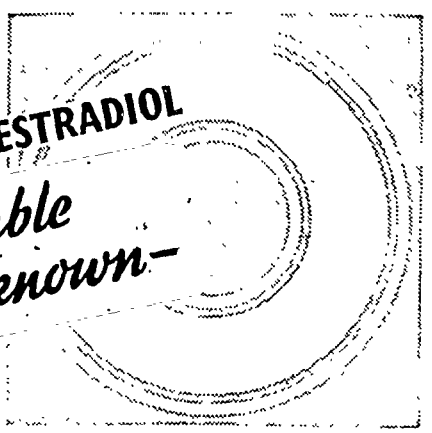
CRYSTALLINE PENICILLIN G EYE OINTMENT *Glaxo*

Contains 25,000 units of penicillin per gram. Such exceptional concentration of the pure crystalline material is well tolerated and encourages penetration into the ocular tissues. *In 1 drachm tubes*

GLAXO LABORATORIES LTD., GREENFORD, MIDDLESEX. BYRon 3434

for prolonged local medication

Penicillin Chewing Gum A&H presents penicillin incorporated in a base predominantly mint-flavoured and designed to maintain the potency of the medicament.



When chewed slowly it provides an effective concentration of penicillin in the mouth for three to four hours. It is thus the preparation of choice in the treatment of Vincent's infection, tonsillitis and other infections due to penicillin-sensitive organisms within the buccal cavity.

PENICILLIN CHEWING GUM A&H

In packets of six pieces, each piece containing 5,000 i.u. penicillin (calcium salt).

200 illustrations make it a pleasure to read. What is most valuable is that the author assumes responsibility for every method that he recommends; he has tested all his methods thoroughly, and he speaks from the standpoint of an immense experience of surgery under local analgesia. Furthermore, general practitioners who look into this book will find in it much which they can put to use in their daily work.—I am, etc.,

Dunedin, N.Z. ROLAND A. H. FULTON.

Penicillin in Emergency

SIR,—The extreme value of penicillin in an acute medical emergency due to a penicillin-sensitive organism is illustrated by the following case.

At 2 p.m. I was summoned to a man aged 81 by his daughter, who stated that her father had developed a shivering attack during the morning and now she did not like the look of him. On arrival, the patient was delirious and restless, trying to sit up in bed. Temperature 104.5° F. (40.25° C.), pulse 100, respirations 40. Patient was oblivious of his surroundings and difficult to examine, and there were few physical signs. A provisional diagnosis of septicaemic pneumonia was made. 500,000 units of penicillin were injected intramuscularly. At 4.30 p.m. the patient was rational, knew his family and myself. Temperature 100.5° F. (38.5° C.). *Sulphathiazole*, 1 g. 4-hourly, by mouth. At 7.30 p.m. the patient was much improved. Temperature 99° F. (37.2° C.), pulse 80. 100,000 units penicillin. The next morning the patient was quite recovered, but somewhat weak. Temperature 97.5° F. (36.35° C.), pulse 70, respirations 16. No abnormal physical signs in lungs or elsewhere.

—I am, etc.,

Leigh-on-Sea. THOMAS REES.

Antiseptics for Minor Dressings

SIR,—With reference to the answer to the question on antiseptics for minor dressings ("Any Questions?" September 17, p. 661), I should like to take your anonymous authority to task for advising the use of proflavine sulphathiazole powder for application to the wounds from minor accidents. I have pointed out previously the dangers of this preparation.[1] Although the incidence of sulphonamide dermatitis due to its local application is not very high in this country, it is an avoidable risk, as sulphonamide is not an essential wound dressing. Sulphonamide dermatitis, particularly the light-sensitive variety, is such a distressing dermatosis that it should be avoided at all costs.

Acriflavine and proflavine have the property of increasing the severity of sulphonamide dermatitis, and Russell and Beck[2] showed that proflavine and sulphonamide mixtures were more lethal to tissues than either substance singly. There is, therefore, even more reason for avoiding proflavine and sulphathiazole mixtures.

As I am afraid that this is so far purely destructive criticism I would like to advise that antiseptics should be avoided as much as possible. The trauma unit at the Royal Infirmary, Sheffield, now uses only "cetavlon" and spirit as pre-operation preparations, and saline and tulle gras as local applications, and there has been a considerable drop in the incidence of contact dermatitis in wounds without noticeable increase in wound sepsis. One still sees, however, a regular supply of cases of sulphonamide dermatitis from those enthusiastic house-surgeons who forget that penicillin powder is 99% sulphathiazole.—I am, etc.,

Sheffield. I. B. SNEDDON.

Myxoedematous Madness

SIR,—I feel I would like to state my opinion that Dr. R. Asher's paper on this subject (September 10, p. 555) is an exceedingly valuable clinical contribution, the importance of which is in no way minimized by the qualifications put forward (September 24) by Drs. E. B. Davies (p. 706) and J. Douglas Robertson (p. 707). Dr. Davies wishes to emphasize that where a psychosis is associated with myxoedema or another endocrinopathy it is not necessarily the result of the endocrine disturbance. This will be readily agreed to, and I do not think that Dr. Asher's article or your annotation intended to indicate otherwise.

However, changes in behaviour pattern, psychoneuroses, and psychoses are not infrequently associated with a major endocrine disturbance—e.g., thyrotoxicosis, myxoedema, adrenogenital syndrome, Cushing's syndrome, Addison's disease, Simmonds's disease, and hypoparathyroidism. When the cure of these disorders or correction of the resulting metabolic disorders is achieved by substitution therapy, operation, or radiation and, following this, the psychoses, etc., disappear, it would seem justifiable to conclude that the endocrinopathy was the immediate cause of the psychoses, the psychoneuroses, or the altered behaviour pattern. This view would not be vitiated by the fact that the psychosis, for example, associated with an endocrine disorder varied in its character and was not constant, because the pattern of the psychotic disorder might well be determined by genetic factors.

I have been particularly impressed by the change in behaviour pattern in patients with hypopituitarism following pregnancy (Simmonds's disease). Whereas hypoglycaemia is an important factor it does not appear to be the sole or constant factor in causing such changes. Of a series of such cases, I have in mind in particular one woman who was a loving wife and mother and who, after the onset of the disease, ceased to have the slightest interest in the well-being of the children or husband, in her own clothes, or in the cleanliness of the household, which deteriorated dramatically. I also recall a woman with Addison's disease whose relatives wrote me after she had been correctly diagnosed and treated that they were deeply grateful for the change in her behaviour and outlook in the home and the return of her normal, kindly, and interested nature. I can hardly consider these features, as well as the major psychoses, chance coincidences.

On the other side of the picture, and in support of Dr. Davies's views, the number of cases one is asked to see of mental disturbances, mental retardations, and delinquencies which have been thought without justification to be of endocrine origin is surprising, although an awareness of the possibility should not be discouraged. Considerable interest has recently been aroused in the general well-being and euphoria produced in patients with rheumatoid arthritis by the use of the pituitary adrenocorticotropic hormone and, on similar lines, by the finding of an increased secretion of adrenocorticotropic hormone after electroconvulsive therapy. It would be prudent, I think, to await further elucidation before becoming excessively enthusiastic about the application of these discoveries to the therapy of psychoses not associated with major endocrine disorders.

As regards the basal metabolism in myxoedema, my experience coincides with that of Dr. Douglas Robertson, and I intimated to Dr. Asher, when he kindly asked me to consider his findings, that uncomplicated myxoedema was usually, if not invariably, associated with a decreased B.M.R.—I am, etc.,

London, W.1. S. LEONARD SIMPSON.

SIR,—The article by Dr. R. Asher (September 10, p. 555) should lead to the more frequent recognition of "myxoedema madness," but in the patient whose condition deteriorates when thyroid extract is administered it should be recognized that it may be dangerous to persist in this form of treatment, as the following short case history displays.

A woman of 58 was admitted to hospital under my care in January, 1949, suffering from confusion and delusions; she appeared to be an obvious case of myxoedema. Treatment with thyroid was commenced (30 mg. thrice daily), but as her confusion increased the dose was doubled. She then became violent and maniacal, refusing to take anything by mouth. This violence alternated with almost complete collapse, when she seemed on the verge of death.

This combination of symptoms suggested that she might be a case of Simmonds's disease, and treatment with testosterone-propionate and desoxycorticosterone was commenced immediately. The improvement was dramatic, and within a few hours she was demanding food. Her condition steadily improved from that date, and her mentality is now almost normal. Her electrocardiograph taken before treatment commenced showed characteristic inversion of the T waves

in the limb leads, which after treatment (except in lead III) have returned to normal. She continues on treatment with testosterone-propionate, but the desoxycorticosterone has been discontinued. Subsequent administration of thyroid has had no beneficial or harmful effect. Her general appearance is still that of myxoedema.

My recognition of this condition was due to an article by A. C. Crooke, clinical endocrinologist, United Birmingham Hospitals (*Practitioner*, 1948, **161**, 298).—I am, etc.,

Maidstone. RONALD LASS.

POINTS FROM LETTERS

Antihistamine Drugs in General Practice

Dr. SIDNEY G. HAMILTON (Woolacombe, N. Devon) writes: There have been many opportunities this summer of trying the new antihistamine drugs in general practice. . . . To be effective, it seems that they should be used early in the treatment. The following two cases are illustrative. (1) After eating strawberries in June a woman of 49 developed an urticarial rash on the face, neck, and right forearm. She treated this with a proprietary cream. She first sought advice two months later. Pyranisamine maleate tablets and cream were prescribed. The irritation was relieved, but the rash showed little improvement. (2) A boy aged 9 was stung by a wasp on the ankle. He had already developed severe symptoms when he was seen 20 minutes later. There was a widespread urticarial rash of the face, body, arms, and thighs. The eyelids and face were swollen, the voice was hoarse, the vision blurred, and he was suffering from violent skin irritation. He was treated with pyranisamine maleate. One ml. of a 2.5% solution was given very slowly intravenously, and 1 ml. subcutaneously. He was also given 0.025 g. of a phenacetin and codeine compound by mouth in order to prolong the action of the drug. The itching of the skin stopped instantly the injection was started, and during the following half-hour the rash and swelling faded gradually. The only abnormal reaction was that of slight nausea. He was seen again four hours later, when he appeared almost normal, though some oedema and rash could still be detected.

Adrenaline in Dysmenorrhoea

Dr. HARRY R. LILLIE (Montreal, Canada) writes: My attention has recently been called by Dr. Cluny Macpherson, of St. John's, Newfoundland, to the use of adrenaline intramuscularly in cases of severe dysmenorrhoea. He has already published his findings under the heading "Pelvic Allergy" in the *Canadian Medical Association Journal* (1949, 60, 54). Following the case of one young girl to whom Dr. Macpherson had had to give morphine (gr. $\frac{1}{2}$ = 32 mg.) and atropine hypodermically before relief was obtained, he recalled having heard a speaker at the St. John's Clinical Society in 1937 refer to certain cases of dysmenorrhoea as due to pelvic allergy, and he reasoned that such should respond to adrenaline as in asthma. His use of 1 ml. of 1:1,000 adrenaline chloride with this girl was dramatic. She had complete relief in ten minutes, with no recurrence for six months, when again adrenaline was just as effective. He has had uniformly good results in all cases of severe dysmenorrhoea since then, and in severe cases has had some success with "benadryl." Shortly after hearing this I had opportunities of testing Dr. Macpherson's recommendations on three of my own patients with acute dysmenorrhoea. One was a young married girl of 26 with an acute retroversion and flexion, and the other two were slightly older women with no malformation. Only the last of the three suffered from constipation as a contributory factor in the trouble. The results have borne out to the full what Dr. Macpherson found.

Medicine in the Popular Press

Dr. J. H. LANKESTER (Oxted, Surrey) writes: It is irritating to find that patients who read magazines such as *Readers Digest*, *Time*, or *Life* have advance, if uncritical, knowledge of new remedies. I would suggest that a regular section of the *Journal*, under an appropriate title, should be devoted to a review of such press claims. This is sometimes done already (e.g., April 2, p. 599, para. 1 of Medical News), but with insufficient prominence or regularity. This section of the *Journal* could also be used for a preview of new drugs or promising lines of research. Critical appraisement can follow later, but the first knowledge of new things should reach us through the medical rather than the popular press.

Public House Hygiene

Dr. A. PHILIP DRAPER (Romford, Essex) writes: Can any action be taken to improve the hygiene, or rather lack of it, in licensed houses? The present system of dipping used glasses into a pail or other receptacle of already grossly contaminated water would appear to serve no useful purpose, in fact quite the reverse.

Obituary

J. TYLOR FOX, M.D., D.P.M.

Dr. J. Tylor Fox, who died on September 20 at the age of 64, was an authority on epilepsy. A son of the late Dr. Hingston Fox, he belonged to the sixth generation of a family of Quaker doctors.

Joseph Tylor Fox was educated at Bootham, the City of London School, Sidney Sussex College, Cambridge, and the London Hospital, where he won the James Anderson Prize for clinical medicine. He qualified in 1910 and graduated M.B., B.Ch. in the following year. In 1916, accompanied by his wife, he went to Russia as chief medical officer of the Friends' War Relief Expedition. He became medical superintendent of the Lingfield Epileptic Colony in 1918, and two years later he proceeded M.D., going on to take the D.P.M. in 1921. During his twenty-eight years as medical superintendent of the Lingfield Epileptic Colony many extensions were made and four new homes were built, the number of patients and staff there increasing to 600. He knew and took a personal interest in each individual under his care, and he early appreciated the crippling social handicaps borne by epileptics.

In 1930 Dr. Tylor Fox became chairman of the new Permanent Committee on Epilepsy, a body formed mainly to obtain statistical data about epileptics. He then went for a three-months tour of institutions in Europe, seeking information and preparing the ground for the resuscitation of the International League against Epilepsy which had lapsed during the 1914–18 war. The International Neurological Congress in London in July, 1935, commemorated the hundredth anniversary of the birth of Hughlings Jackson. It was particularly appropriate, therefore, that, mainly due to the energy of Dr. Tylor Fox, over thirty doctors attending the congress from fifteen different countries should visit Lingfield and bring the International League against Epilepsy into being again. Dr. William G. Lennox (U.S.A.) was made president; Dr. Schour (Denmark) and Dr. Muskens (Holland) secretaries; and Dr. Tylor Fox was treasurer. Later Dr. Fox persuaded the then Central Association for Mental Welfare, now the National Association for Mental Health, to form a special committee on epilepsy to help epileptics in the community. Dr. Tylor Fox became chairman of this committee and continued in that office until his death.

Dr. Fox retired from Lingfield in 1946, having seen the colony through the war years. Although in poor health, he then devoted much time to a campaign for greater understanding and sympathy towards epileptics. He wrote articles on this theme for both medical and lay publications. Among his articles on the clinical aspects of epilepsy was "Rhythm in Epilepsy," written in collaboration with Dr. Gwenvron Griffiths. This was a survey of the incidence of fits in a group of epileptics over a long period.

Dr. Fox married Elsie, daughter of the late Edwin Gilbert, and she survives him with two sons and a daughter; both sons are following in the family medical tradition.

Dr. Denis Williams writes: Although Tylor Fox will be remembered with deep affection by thousands of epileptic patients, he will have influenced the lives of many more to whom he was quite unknown. He was in the long line of English social reformers, and like so many of them he was quiet and retiring, only expressing himself under the stimulus of other people's needs. He was first of all a personal physician, who in the Lingfield colony had an experience of the medical and social treatment of epilepsy

which cannot have been surpassed. It happened that his work there covered the years of therapeutic advance, when the barbiturates and then the hydantoins became widely used. In that time, too, the electroencephalogram began to throw light on an obscure disease. As each new piece of knowledge appeared he sought it out and applied it. Although he was an expert in this field he did not write much, for he was too reticent, but his opinion, sought personally, was careful and experienced. Perhaps it was more than reticence that limited his writings; perhaps it was that Tylor Fox was more concerned for people with epilepsy than for epilepsy. In the social care of his patients he was both eloquent and active, and that activity went far beyond his own colony. Although he had retired from Lingfield, when he died he was president of the British branch of the International League against Epilepsy, and chairman of the epilepsy committee of the Association for Mental Health, as well as chairman of the Lebanon Hospital in Beirut, like his uncle before him. Through these bodies he continued his work, but he still did much by personal contact and persuasion. He was always concerned with problems of education, of employment, and of public enlightenment for the good of the epileptic. When he was absent from the recent meetings in Paris there were inquiries about his welfare and work from those interested in epilepsy in many of the countries of Europe and of the States of America. His work has made him very widely known.

Dr. Denis G. Kennedy writes: When Dr. Fox handed over Lingfield Epileptic Colony to me in the summer of 1946 he was a very tired man. The running of the colony during the war years, perhaps more than any other similar institution, had been a work of extraordinary difficulty. Dr. Fox had two great interests in life—namely, his clinical work and his social work on behalf of epileptics—and during his later years at Lingfield he had found the administrative duties of his post take a heavier and heavier toll of his time and energies. He was, I think, glad to hand over his administrative work, and looked forward keenly to devoting the whole of his time to what had become his main interest—the removal from the public mind of prejudices concerning the epileptic. His single-mindedness in the pursuit of this aim, born as it was of his keen sense of social service, had an intensity rather strange to see in a post-war world of disillusion and apathy. He was a man of great tolerance to the frailties of human nature, and in consequence made many lasting friends. Up to the very last he was working hard in the cause he had made his own, and his tragic death leaves a painful void in the circle of people whose lives are devoted to the care of epileptics. At Lingfield Colony he has left a name which will be remembered with affection and esteem for a very long time.

R. E. BICKERTON, D.S.O., M.B.

Mr. Reginald Ernest Bickerton, the well-known ophthalmic surgeon, died peacefully on September 13 at the age of 79, after two years of steadily failing health. His father was Thomas Bickerton, F.R.C.S.Ed., of Liverpool, and he was a student at Liverpool University, where he graduated M.B., Ch.B. in 1895. He was successively house-physician, house-surgeon, ophthalmic assistant, and senior resident medical officer at the Liverpool Royal Infirmary. Later he visited and held ophthalmic appointments in Berlin, Vienna, Munich, Utrecht, and Zurich. After his marriage in 1899 he settled in London and was appointed ophthalmic surgeon and lecturer to the "Dreadnought" Seamen's Hospital, Greenwich. Mr. Bickerton served this hospital for 42 years, a record hardly equalled throughout its long history. On the advent of the National Health Service he received the unusual honour of being unanimously elected a vice-president of the hospital.

Mr. Bickerton was consulting surgeon to the Hornsey Central Hospital, the Royal Waterloo Hospital, London, and the Evelina Hospital for Sick Children. The late Sir Arthur Pearson personally put him in charge of blinded soldiers and sailors at St. Dunstan's, which post he held from the end of the 1914–18 war until the outbreak of the second world war, when the blinded ex-Servicemen were removed from London. He was also ophthalmic surgeon to the Children's Clinic, Marylebone Road; chairman and honorary ophthalmic surgeon to the Royal School for the Blind at Leatherhead; and chairman of the Hawksley Pension Fund for the Blind of the professional classes. He acted as a medical referee for ophthalmic cases under the Workmen's Compensation Act, and was visiting ophthalmic surgeon to the Ministry of Pensions Hospital, Richmond.

He joined the Territorial R.A.M.C. in 1909 in response to Lord Roberts's urgent appeal at that time, and was promoted captain in 1912. He was mobilized in 1914, though over age, and later with the rank of lieutenant-colonel he commanded the 84th (London) Field Ambulance, which was attached to the 28th Division, serving in the British Expeditionary and Salonika Forces, in the Army of the Black Sea, and in Belgium, Turkey, and Asia Minor. He was appointed A.D.M.S. of the Army of the Black Sea in 1919 and was twice mentioned in dispatches. He had been awarded the D.S.O. in 1917, and he was appointed honorary surgeon to the King from 1927 to 1932. Since 1932 he had been honorary colonel of the 56th Division (1st London) T.A. Mr. Bickerton was responsible for a number of contributions to the literature of his specialty, and he was particularly interested in mustard gas burns affecting the eyes. He was honorary secretary of the Section of Ophthalmology at the Annual Meeting of the B.M.A. in 1927 and vice-president of the Section in 1938.

Mr. Bickerton was held in great esteem by his patients and his colleagues, and indeed by all who came in contact with him. His gentle but firm behaviour, his old-world courtesy, and his loyalty to his friends were as impressive as his undoubted skill as an ophthalmic surgeon. He endeared himself to everyone, and his name will always be held in affection by his many friends and particularly by those blinded officers and men for whom he cared. He took much more than a professional interest in them, and they greatly appreciated his wise and generous friendly advice. In the same way there must be thousands of merchant seamen who are grateful both for his skill and for his kindness.

A requiem mass was held on Monday, September 19, at All Saints, Margaret Street, W.1, of which for some years, till his health failed, Mr. Bickerton had been churchwarden. There many representatives of the medical profession, of St. Dunstan's, of the Seamen's Hospital, and of the blind and staff of the Royal School for the Blind, and many others paid tribute to his memory.

G. C. WILLIAMS, O.B.E., M.R.C.S., D.P.H.

Dr. Geoffrey Commeline Williams, who was senior administrative medical officer to the Oxford Regional Hospital Board, died on September 21 at the age of 57. He was born at Thornbury, Gloucestershire, where his father was in medical practice, and was educated at Clifton College, Caius College, Cambridge, and Bristol. In 1916 he qualified, and he went on to take the Bristol D.P.H. in 1921. He took the Cambridge M.A. degree before starting his clinical studies, and he was also, by incorporation in 1937, M.A.(Oxon), becoming a member of Brasenose College. In the 1914–18

war he served overseas as a captain in the R.A.M.C. For a short time after demobilization he filled the post of assistant medical officer to the Bristol City Fever Hospital and Sanatorium.

Dr. Williams came to Oxford as assistant medical officer of health in 1921, becoming deputy M.O.H. later. In 1930 he was appointed medical officer of health to Oxford County Borough Council. He was awarded the O.B.E. in 1942 for his services to public health generally and to civil defence in particular. It was in October, 1947, that he became senior administrative medical officer to the Oxford Regional Hospital Board. Dr. Williams was a Fellow of the Society of Medical Officers of Health, a Fellow of the Royal Sanitary Institute, an officer of the Order of St. John, and county surgeon to the St. John Ambulance Brigade. He was formerly an examiner in public health to the University of Oxford, a past chairman of the Oxford and District Public Medical Service, and a member of the committee of the Nuffield Institute of Social Medicine and of the Council of the medical staff of the United Oxford Hospitals. He was also a member of the joint county committee of the British Red Cross Society and the Order of St. John. In 1936 he was vice-president of the Section of Public Health at the Annual Meeting of the B.M.A. He married Irene Mary Durant in 1919, and she survives him with one daughter.

W.S. writes: Men like "Billy" Williams can ill be spared at any time, least of all in these days when so much hinges on a fair and equitable administration of the new health services. While medical officer of health for Oxford, and more recently as senior administrative medical officer to the regional board, his faith and trust in the members of his staff drew forth the most profound loyalty from each and everyone, and he inspired the confidence of the profession and public alike. He was a first-class administrator, and approached the innumerable problems much more from the human side than from the point of view of regulations and orders, if they happened to be incompatible. He was perhaps at his best in times of stress, when his calm and equable character shone forth conspicuously. His discreet and tactful intervention at committee meetings many times smoothed out what might have developed into an awkward situation. Only his intimate friends knew how much help he gave to others in trouble or difficulties. Like so many others in both wars, he lost the opportunity of proceeding to higher degrees by volunteering for service in the Forces immediately after qualifying. Williams was a man of the highest integrity, and everyone with whom he came into contact soon recognized his quality. While medical officer of health for Oxford his relations with the general practitioners were particularly happy. He had few hobbies, but until he became absorbed in civil defence duties he enjoyed a round of golf, at which he was quite a fair performer. There was a pathetic appropriateness in the fact that he spent the last days of his life in the Slade Hospital, a modern institution for infectious diseases for the construction and planning of which Williams was largely responsible. His death has left a feeling of intense sadness in many Oxford homes, and there will be deep heartache among those who were privileged to be associated with him in his many activities. To his courageous and devoted wife and daughter the deepest sympathy will be extended by all who knew him.

G. J. STEFANOPOULO, M.D.

When a French military aeroplane landing at Pointe Noire on September 19 burst into flames, French tropical medicine lost one of its most distinguished exponents. Dr. G. J. Stefanopoulo, who was one of the eighteen people killed in this accident, was a *chef de service* at the Pasteur Institute in Paris. He was born in Greece in 1893 and was educated at the Universities of Athens and Montpellier. After service in the first world war he became an assistant to Professor Auguste Pettit, and with him did much to elucidate the part played by pathogenic leptospira in the causation of leptospirosis icterohaemorrhagica. When Noguchi claimed that yellow fever was due to a spirochaete Stefanopoulo's interests became centred in yellow fever. As a result of his visits to tropical Africa he mapped out the distribution of yellow fever in the French African Colonies, and in collaboration with British workers he was the first to point out the significance of monkeys in the maintenance of yellow fever in Africa.

In accordance with the traditions of the Pasteur Institute he early focused his attention on the possibilities of immunization against yellow fever, and his laboratories in Paris have for many years been immunizing nearly 40,000 persons a year. On one of his many visits to Africa he became infected with *Loa loa*, for which at the time there was no satisfactory treatment. Stefanopoulo was one of the first to use hetrazan not only curatively but prophylactically against filarial infections. At the time of his death he was visiting French Equatorial Africa at the request of the Minister for the Colonies to advise on how living conditions could be improved for Europeans working in the Tropics.

During the recent war Stefanopoulo was a member of the resistance movement. He was a great admirer of this country, where he was well known and had many friends. He took part this year in the discussions of the Section of Tropical Medicine at the Annual Meeting of the British Medical Association at Harrogate and read a paper on his investigations on *Loa loa* infection. For many years before the second world war Stefanopoulo represented Greece at the meetings of the Office Internationale d'Hygiène Publique. He was a member of the Greek Academy of Medicine and an Officer of the Legion of Honour. The sympathy of many friends in this country will be extended to his wife and two young children in their tragic loss.—G. M. F.

Dr. Donald Ross, who was formerly medical superintendent of the Argyll and Bute mental hospital, died at Ardrannich, Inveraray, on August 25. Dr. Ross received his early education in Switzerland and at Dollar Academy, where he achieved distinction in his studies and in sport, winning the medal for modern languages in his final year. At Edinburgh University he graduated M.B., Ch.B. in 1908, and subsequently held appointments at Edinburgh Royal Infirmary, Melrose Institution, Edinburgh Royal Asylum, and Glasgow Royal Asylum. He was appointed medical superintendent of the Argyll and Bute Mental Hospital, Lochgilphead, in 1914, and this appointment he held until his retirement in August, 1946. Dr. Ross was admitted M.R.C.P.Ed. in 1928. He was a secretary of the Caledonian Medical Society and a committee member of the Royal Medical Psychological Association, which he represented on several occasions at international congresses. He was a founder of the Campbell Clark Medal for Mental Nursing, and made a number of contributions to the medical literature. He was chairman of the Argyll Division of the British Medical Association in 1934 and again in 1939. Following the promise of earlier years he became a fluent linguist in eight languages—French, German, Gaelic, Flemish, Italian, Arabic, Urdu, and Spanish. He learned Gaelic after his appointment at Lochgilphead so that he could converse freely with patients who knew no other language. For several years he was a member of the executive council of An Comunn Gaidhealachd and secretary of Mid-Argyll Branch. He was an authority on ancient monuments, particularly those in and around Argyll, and a Fellow of the Society of Antiquaries. Dr. Ross was associated with the Territorial Army from its inception in 1908, and served as

'AVLON'

PENICILLIN PREPARATIONS

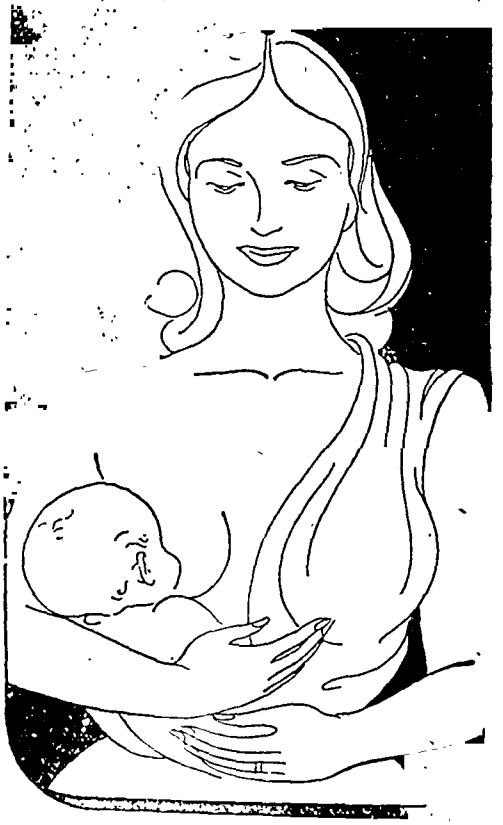
LOZENGES OF PENICILLIN
Each lozenge contains 500 units either of the Calcium (B.P.), or Crystalline Potassium Salt of Penicillin. *In containers of* 20 *and* 500.

CRYSTALLINE PENICILLIN WITH 'SULPHAMEZATHINE' (STERILIZED)
Containing 5,000 units of Crystalline Potassium Penicillin per gramme. *In bottles of 25 grammes.*

CRYSTALLINE PENICILLIN WITH SULPHANILAMIDE (STERILIZED)
Containing 5,000 units of Crystalline Potassium Penicillin per gramme. *In bottles of 25 grammes.*

OINTMENT OF PENICILLIN, B.P.
Containing 500 units of the Calcium Salt of Penicillin per gramme. *In tubes of 25 grammes.*

PENICILLIN OINTMENT FOR THE EYE, B.P.
Containing 1,000 units of the Calcium Salt of Penicillin per gramme. *In tubes of 5 grammes.*



'AVLOPROCIL'
Brand of Procaine Penicillin G Oily injection.
In vials of 10 *c.c., singly and in boxes of* 5.

Literature and further information available, on request, from your nearest I.C.I. Sales Office—London, Bristol, Birmingham, Manchester, Glasgow, Edinburgh, Belfast and Dublin.

IMPERIAL CHEMICAL (PHARMACEUTICALS) LTD.
A subsidiary company of Imperial Chemical Industries Limited
WILMSLOW, MANCHESTER

Ph.3

PREGNAVITE

a single* supplement for safer pregnancy

CLINICAL USES

To improve the nutritional state where circumstances prevent consumption of all the protective foods required; to prevent hypochromic anæmia.

Indications in the history of previous pregnancies: toxæmia, previous premature births, inability to breast feed and dental caries.

* The recommended daily dose provides: vitamin A 2,000 i.u., vitamin D 300 i.u., vitamin B_1 0.6 mg., vitamin C 20 mg., vitamin E 1 mg., nicotinamide 25 mg., calc. phosph. 480 mg., ferr. sulph. exsic. 204 mg., iodine, manganese, copper, not less than 10 p.p.m. each.

REPAIR TO HAND

Fixation with Elastoplast

A Battle Casualty with considerable destruction of the palm of the hand, the little finger and the fifth metacarpal joint. Skin grafting was carried out as a preliminary measure to produce a healed surface. Later there was excision of graft and scar tissue with application of a direct flap from the back. Fixation was secured with Elastoplast prior to division of the base of the flap.

The details and illustrations above are of an actual case. T. J. Smith & Nephew Ltd., of Hull, manufacturers of Elastoplast, publish this instance — typical of many, in which their products have been used with success.

a captain in the 1914–18 war and as a colonel in the recent war. Between the two wars he was regimental medical officer of the 8th Argyll and Sutherland Highlanders, and for his services was awarded the M.B.E. and the T.D. Throughout his life he was keenly interested in sport and played rugby for Edinburgh University, the Melrose, Hawick, and Jedforest clubs, and for the Army against France as wing three-quarter. While a student he won medals for 220 yards flat races on two occasions, and in later years he was a judge of racing and heavy events at the Highland Gatherings at Oban and Mid-Argyll. It was his invariable custom before the war to walk over the hills alone from Lochgilphead to the Oban Games, and after the games he made the return journey by the same route. Dr. Ross was deeply interested in the welfare of the county, and was an elder of Lochgilphead Parish Church, a local justice of the peace, and a founder of Lochgilphead Ex-Servicemen's Institute. He is survived by his wife, four sons, and four daughters. Two of his sons are in the medical profession, and one of his daughters is the matron of Argyll and Bute Mental Hospital.—J. A. A.

Dr. Basil John Francis Jackson-Taylor, who died on August 18, had spent 38 years in general practice. He was a student at King's College Hospital, and qualified in 1904. After some years spent in resident hospital appointments at the London Temperance Hospital and at Bagthorpe Infirmary, Nottingham, he settled in practice at Hucknall, Notts, where he built up a large general practice from which he retired in 1926. He then took a small practice in Horley, Surrey, intending to lead a quieter life. However, his qualities soon led to such demands for his services that it was many years before he was able to secure the leisure which he desired and needed. Dr. Jackson-Taylor had for 20 years been divisional surgeon to the St. John Ambulance Brigade, a unit which he had largely helped to build up in Horley. He was for many years a member of the executive committee of the Reigate Division of the B.M.A., and was chairman of the Division during 1935 and 1936. He took a prominent part in the discussions preceding the present National Health Act and did not conceal his doubts about the wisdom of that measure, an opinion with which many of his past opponents now agree. He was a man of shrewd insight and clinical ability, with an equable mind and a kindly disposition. Never did these qualities show to better advantage than at the time during which he well knew what lay before him. A large circle of friends, colleagues, and patients have learned of his passing with deep regret.—K. W.

Dr. William Stewart, of Denton, died at his home there on September 3. He was one of the best-known practitioners in the district and had always taken an active part in local affairs. William Stewart was born in Ireland, and graduated at Queen's College, Belfast, in 1887. As a student he won the prize in surgery in 1886. He was at Longton, Staffs, as a locumtenent for a short time and later at Salford. Then in 1888 he settled in Denton and was in general practice there for 57 years. Dr. Stewart's association with the St. John Ambulance Brigade began as long ago as 1903. He lectured to both the ambulance and nursing divisions for many years, and he was promoted a Commander of the Order of St. John of Jerusalem in 1932. During the 1914–18 war he was in charge of the Denton Red Cross Hospital, and in September, 1939, he was appointed honorary medical officer for the Denton first-aid post. Dr. Stewart was honoured in 1944 with the insignia of Knight of Grace of the Venerable Order of St. John, and in 1945 he was presented with an illuminated address paying tribute to his services as a general practitioner and as medical officer of health to the district from 1910 to 1939. Dr. Stewart was one of the old type of family doctors who earned and held not only the esteem but the affection of all his patients.

Dr. James Kearney, of Wanstead, London, E.11, died suddenly on September 5 while on holiday. He qualified at Dublin in 1913, and in the first world war he served as a captain in the R.A.M.C. After demobilization he went into general practice in Leytonstone and became a partner in one of the oldest established practices there. Among the appointments that he held were those of district medical officer for Leyton, honorary medical officer of the Essex County Nursing Association, and during the recent war he served on the National Service medical boards and in the Home Guard. He took a keen interest in the work of the Leytonstone Branch of the British Legion and in many other local activities. Possessed of a strong personality, Dr. Kearney was well known for his forthright manner. He was an outstanding example of the old-type family doctor, and he was much loved by all his patients, knowing every detail of their personal and family history and always giving them unstinted service. His practice was his all-absorbing interest, and in spite of failing health he carried on to the last, dying, as he had wished, in harness. He is survived by his widow, one son who is studying medicine, and two daughters, to whom the sympathy of his colleagues and friends will be extended.

Dr. Harry Smith, who died on September 16 at the age of 48, was a popular and influential figure in the public health service of London. Dr. Smith was one of the nine divisional medical officers appointed to administer the local health authority services of the London County Council. He took up this post in April, 1948, and was in charge of the division which included Chelsea, Fulham, Hammersmith, and Kensington. His energy, his skill in health administration, and his ability to get on with all types of men, women, and, above all, children eased the process of establishing the new structure. Dr. Smith's easy charm, his wide knowledge of the law and practice of public health, and his ready adaptability to new circumstances quickly gave him a high reputation among his colleagues, the members of the divisional health committee, and the wide section of the population with whom he came into contact. Resolutions of appreciation of his service have already been sent from several of the voluntary organizations in his division. Dr. Smith was a student at St. Bartholomew's Hospital. After qualifying in 1924 he held resident appointments in hospitals in Rugby and London before going into general practice for five years. He used to look back at this part of his career, spent in rural practices in the West of England, with particular affection, and to say that the intimacy of the personal contacts one was able to make in general practice provided a quality which was never attainable in other branches of the profession. For two years Dr. Smith was an assistant school medical officer at Plymouth and then, from 1934 for four years, assistant medical officer of health at Portsmouth. His varied experiences in these appointments were part of the equipment which made him so valuable when he joined the London service in 1938. His first important work in London was in the slum-clearance programme which before the war constituted a large and important part of the department's functions. During the war he undertook duties connected with the school health service, the medical examination of staff, first-aid training, and other problems. He was promoted to divisional medical officer in 1941, and principal assistant medical officer in 1946. On his way to work in 1944 he was nearly killed by a bomb which fell in York Road just outside Waterloo Station. The memorial service at St. Mary Abbot's Church, Kensington, was attended by a large and representative gathering of friends and colleagues who mourned the departure of one whose personal qualities they loved and whose devotion to the public service was a source of inspiration to all who knew him.—A. D.

The Nurses and Midwives Whitley Council has agreed on higher salaries for ward sisters, charge nurses, deputy ward sisters, deputy charge nurses, and staff nurses employed in mental hospitals, and for midwives employed in maternity hospitals and homes and maternity units or wards of other hospitals. The increases are consequential to the agreement reached previously for nurses employed in general hospitals. The Whitley Council has also agreed on the salaries of part-time enrolled assistant nurses, staff nurses, and ward sisters who are employed in general hospitals. Nurses employed for not more than 40 hours a week will be paid on a sessional basis. For a session of four hours the rates are: enrolled assistant nurse, 10s.; staff nurse, 11s.; ward sister, 13s. 4d. In addition meals on duty will be given and uniform provided and laundered free.

Medico-Legal

DEATHS FOLLOWING INJECTIONS OF CONVALESCENT MEASLES SERUM

Mr. W. Bentley Purchase, coroner for St. Pancras, on September 26 concluded an inquiry into the deaths of three children—Pauline Hallett, Richard Taviner, and Brian Wood, all of Hornsey, and all aged 3 years.

Dr. John Harrington, of the Central Public Health Laboratory, Colindale, said that on July 1 he injected a number of children at a day nursery with anti-measles serum. Five children received injections from one particular batch of serum, and three of these were the children who had died. All were measles contacts, and none of them had a history of measles. These five children were not injected consecutively, but were spaced out among a number of others. The only point in common in the case of the five was that they received serum from the same batch. The syringes were changed after every fourth injection, and a fresh needle and a fresh charge of the syringe were used for each child.

Dr. W. C. Cockburn, also of the Central Public Health Laboratory, Colindale, said that the batch in question was known as "309." Asked how it came about that only five children were inoculated from this particular batch, he said that that was just as it happened; there was only a small amount of serum available at the time. There was no selection about it. There was no reason to suspect any difference between this batch and other batches. The experience of the other children inoculated on the same day from the other batches presented nothing of significance. There was no reason to doubt that the syringes were perfectly sterilized.

Dr. R. A. Zeitlin said that the Blood Transfusion Department of the Central Laboratory had collected this serum from 60 normal adults. So far as was known there was nothing to arouse suspicion serologically. Among the 60 it had been discovered that five had had jaundice, but in all cases the attack took place very many years ago, far earlier than the beginning of any danger period. He agreed with the coroner that, lamentable as these three deaths were, the public danger, having in mind the large numbers continually served from his laboratory, was infinitesimal.

Dr. F. E. Camps said that the boy Taviner and the girl Hallett both showed at post-mortem examination a necrosis of the liver, which was rather less marked in the girl. Dr. Alfred Piney said that he had made a post-mortem examination of the boy Wood, and here too there could be no doubt that death was due to necrosis of the liver.

The coroner said that he was entirely satisfied from the evidence of Dr. Harrington, who gave the injections, and of Dr. Zeitlin, who was in charge of the laboratory from which the serum was obtained, that there was no obvious source of infection or anything of that kind. There was no sort of neglect or lack of care. In each case he returned a verdict of "Death by misadventure."

Universities and Colleges

UNIVERSITY OF LEEDS

The inaugural lecture of the Faculty of Medicine will be given in the Riley-Smith Hall of the University Union on Friday, October 7, at 3 p.m., by Professor John Cruickshank, C.B.E., M.D. His subject will be "Medicine, To-day and To-morrow." Members of the medical profession are invited.

UNIVERSITY OF SHEFFIELD

Mr. E. F. Finch, M.D., M.S., F.R.C.S., vice-president of the Royal College of Surgeons of England, will deliver the opening sessional address of the Faculty of Medicine in the Firth Hall of the University on Friday, October 21, at 5 p.m. His subject will be "The Evolution of Medical Education."

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended September 10. [No. 36

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

‖ Includes puerperal fever for England and Wales and Eire.

EPIDEMIOLOGICAL NOTES

Poliomyelitis

The total number of notifications in the week ended September 17 was: poliomyelitis 311 (284), polio-encephalitis 31 (22). Figures for the previous week are shown in parentheses. These are the highest recorded this year.

Multiple cases (poliomyelitis and polio-encephalitis together) were reported from the following counties: London 41 (31), Berkshire 7 (4), Chester 4 (6), Cornwall 10 (3), Devon 5 (5), Dorset 3 (5), Durham 7 (7), Essex 18 (16), Gloucester 15 (10), Hertford 4 (5), Kent 16 (9), Lancaster 29 (38), Leicester 13 (7), Lincolnshire, Kesteven 5 (2), Lincolnshire, Lindsey 7 (1), Middlesex 25 (19), Norfolk 3 (1), Northampton 3 (1), Northumberland 10 (8), Nottingham 11 (16), Somerset 8 (3), Southampton 10 (15), Stafford 3 (4), Surrey 14 (9), East Sussex 2 (4), Warwick 10 (10), Wiltshire 6 (8), Yorks East Riding 5 (4), Yorks North Riding 2 (1), Yorks West Riding 33 (25), Glamorgan 3 (7).

In 1947 the total figures for the corresponding week were poliomyelitis 572, polio-encephalitis 42. In 1947 this was the week in which the fall in notifications began.

Discussion of Table

In *England and Wales* there was a decrease in the notifications of whooping-cough 387, measles 293, and dysentery 39, while the largest increase was in the incidence of scarlet fever 28.

The fall in the incidence of whooping-cough was contributed by a few areas, notably Lancashire 60, Middlesex 55, Yorkshire West Riding 39, Northamptonshire 39, and Lincolnshire 23. In most areas there was a fall in the incidence of measles, and for the first time since the beginning of 1946 notifications fell below 1,000 a week. No variations of any size occurred in the local trends of scarlet fever. About one-third of the total cases of scarlet fever were notified in three areas—London, Lancashire, and Yorkshire.

Notifications of diphtheria were 13 more than in the preceding week. The largest increases were Staffordshire 6 and Lancashire 5; London 9 and Liverpool 8 accounted for one-quarter of the total notifications of diphtheria.

Of the 20 cases of paratyphoid fever 10 were notified in the county boroughs of Lancashire. A further 11 cases of dysentery were notified in Northumberland, Gosforth U.D., where 21 cases were notified in the preceding week. In Liverpool C.B. 9 cases of cerebrospinal fever, one-quarter of the total cases, were notified.

Notifications of food-poisoning came from London 32 (Islington 12); Essex 63 (Southend-on-Sea C.B. 33, Ilford M.B. 14); and Gloucestershire 20 (North Cotswold R.D. 11).

In *Scotland* there was an increase in the notifications of dysentery 17 and scarlet fever 10, with a decrease in the incidence of whooping-cough 10. An outbreak of dysentery with 13 notifications occurred in Stirling county; other centres of infection were Glasgow 59 and Edinburgh 8. In Glasgow the notifications of scarlet fever rose from 28 to 43.

In *Eire* there was a rise in the notifications of whooping-cough 26 and scarlet fever 19, with a decrease of 20 in the notifications of diarrhoea and enteritis. The incidence of diarrhoea and enteritis remained high in Dublin C.B., with 115 notifications.

In *Northern Ireland* an increase was reported in the notifications of measles 23 and scarlet fever 18.

Quarterly Return for Scotland

The birth rate during the June quarter was 19.7 per 1,000, and was 0.7 below the average of the five preceding second quarters. The infant mortality rate was 36 per 1,000 registered live births, being 15 below the five years' average and the lowest rate ever recorded for any quarter in Scotland. The general death rate was 11.8 per 1,000 and was 0.1 below the five years' average. The death rate from all forms of tuberculosis was 69 per 100,000, and from respiratory tuberculosis 60; these rates were respectively 15 and 11 below the rate for the second quarter of 1948 and 13 and 3 below the five years' average. Deaths attributed to the principal epidemic diseases numbered 111, being 39 more than in the second quarter of 1948. These deaths include 62 from influenza, 25 from whooping-cough, 11 from cerebrospinal fever, and 9 from measles. Deaths from violence numbered 662, and were 74 more than in the second quarter of 1948, although deaths attributed to road accidents declined by 7.

Week Ending September 17

Notifications of infectious diseases in England and Wales during the week included: scarlet fever 942, whooping-cough 1,180, diphtheria 78, measles 688, acute pneumonia 211, cerebrospinal fever 34, acute poliomyelitis 311, acute polio-encephalitis 31, dysentery 86, paratyphoid fever 18, typhoid fever 4, food-poisoning 267.

Medical News

Barrow-in-Furness Clinical Society

Meetings of this society, which lapsed during the war, are to be held again. The society intends to meet at 8 p.m. on the fourth Tuesday in each month from October to March inclusive, usually at the Orthopaedic Clinic, North Lonsdale Hospital. The subscription is 5s. a year. Particulars may be obtained from the secretary, Dr. John Fawcitt, Fountain Street House, Ulverston, Lancs.

Smoke Abatement

The Public Health (Smoke Abatement) Act, 1926, empowers the Minister of Health to make orders extending the provisions of the Alkali, etc., Works Regulation Act, 1906. Orders have been issued at various times extending the list of noxious or offensive gases mentioned in the Act of 1906, and extending the list of scheduled works requiring registration under the Act. A draft Order has now been prepared further extending the list of gases and works. A public inquiry will be held into the subject matter of the draft Order at the offices of the Ministry of Health, Caxton Hall East, Tothill Street, London, S.W.1, on October 18 at 2.30 p.m. It will be open to the Press, and any interested person may attend and give evidence. Copies of the draft order may be seen at the Ministry of Health, Whitehall, or purchased either directly or through any bookseller from H.M. Stationery Office.

Société d'Hématologie

At the recent meeting of the Société Internationale Européenne d'Hématologie, held at Montreux, Dr. A. Piney was elected vice-president of the society.

Lead Nipple Shields

The Ministry of Health has informed executive councils of evidence that lead encephalopathy in babies has been caused by mothers using lead nipple shields. A notice on the subject is being sent to medical practitioners and chemists, and the entry in the Third Schedule of the General Medical and Pharmaceutical Services Regulations, 1948, will be amended as soon as practicable to exclude lead nipple shields.

Contaminated Milk

The powers of local authorities and medical officers of health are extended under the Food and Drugs (Milk and Dairies) Act, 1944, which comes into operation on October 1 of this year, and its subordinate legislation. The supply of milk may now be stopped in respect of any disease communicable to man by consumption of milk; the powers formerly extended only to infection with notifiable disease, including dysentery.

Wills

Dr. William James Bennett-Jones, formerly consulting anaesthetist to the Royal Liverpool United Hospital, left £6,860. Dr. Graham Lionel John Wilson, of Teddington, Middlesex, left £20,347; Dr. Henry Winstanley, of Billinge Higher End, near Wigan, £18,695; Surgeon Commander Albert Brooke-Bateman, R.N., £1,854; and Dr. Haldinstein David Haldin-Davis £36,882.

COMING EVENTS

Hunterian Society

The Hunterian Society has arranged a party to be held at Gunter's, 6, Stanhope Gate, London, W., on Thursday, October 6, at which there will be an exhibition of the society's history and relics of John Hunter, together with an important series of legal documents relating to his life and of his little-known son, J. B. Hunter, which has recently come into the possession of the society.

Lectures: The Design of Experiment

The Oil and Colour Chemists' Association (Aldwych House, Aldwych, London, W.C.2) has arranged three postgraduate lectures on "The Design of Experiment—The Development of Experimental Methods and Theoretical Ideas in a Field of Research" to be given by Professor M. G. Evans, D.Sc., F.R.S., at the Royal Institution, 21, Albemarle Street, London, W., on Thursdays, October 6, 13, and 20, at 6.30 p.m. The inclusive charge for the course to members and visitors is 10s., and applications for tickets should be sent in advance to John Hannaford, secretary and treasurer, at the above address. Admission to junior members is free of charge, but those interested must apply for complimentary tickets.

Royal Dental Hospital of London

The prize distribution and conversazione of the Royal Dental Hospital of London School of Dental Surgery (University of London) will be held at the Royal Dental Hospital, 32, Leicester Square, London, W.C., on Friday, October 7, at 8 p.m.

Birmingham Regional Consultants Committee

The Birmingham Regional Consultants and Specialists Committee will hold a meeting at the Queen Elizabeth Hospital on October 11 at 5.15 p.m. Items on the agenda include reconstitution of the committee and grading. Members are asked to obtain from their groups information about these subjects.

National Society of Children's Nurseries

A conference on "The Training and Examination of the Nursery Nurse as seen in 1949" has been arranged by the National Society of Children's Nurseries (Norfolk House, Norfolk Street, Strand, London, W.C.2), to be held at County Hall, Westminster Bridge, London, S.E., on Friday, October 14, from 11 a.m. to 5 p.m. The speakers will be Sir Allen Daley, M.D., F.R.C.P., K.H.P., Dr. Ruby N. E. Pike, Miss Hilda Hincks, Mr. H. W. Brand, Miss D. E. Harvie, Miss H. Howse, Mrs. A. Creech Jones, and Mr. J. H. Lloyd. Tickets of admission may be obtained from the honorary secretary of the society at the above address.

Royal Institute of Public Health and Hygiene

A series of lectures will be given at the Royal Institute of Public Health and Hygiene, 28, Portland Place, London, W., on Wednesdays, at 3.30 p.m., from October 19 to November 30. Details will be published in the diary column week by week. Admission to the lectures is free, without ticket.

The Tutor in the N.H.S.

A conference on "The Tutor in the National Health Service" will be held at the Royal College of Nursing, Henrietta Place, Cavendish Square, London, W., on Monday, Tuesday, and Wednesday, November 14, 15, and 16. Tickets of admission may be obtained from the conference secretary of the College at the above address before October 15.

SOCIETIES AND LECTURES

Saturday

ST. STEPHEN'S HOSPITAL (RHEUMATISM UNIT), 369, Fulham Road, London, S.W.—October 1, 10 a.m., "*Some Social and Economic Aspects of the Chronic Rheumatic Diseases*," introductory address by Sir Ernest Rock Carling; 11 a.m., "*Some Modern Aetiological Concepts and Clinical Variants of Rheumatic Joint Diseases*," by Dr. Philip Ellman; 12 noon, "*The Management of the Rheumatoid and Osteoarthritis Types of Chronic Arthritis*," by Dr. Francis Bach; 2 p.m., "*Ward Round and Demonstration of Methods of Physical Treatment Injection and Plaster Technique*," by Dr. Francis Bach and medical registrars; 3 p.m., "*Social Welfare, Dietetics, Occupational Therapy, and Vocational Guidance*," by Dr. Francis Bach and members of the staff of Rheumatism Unit; 4.15 p.m., "*Clinical Pathology in Gout and the Rheumatic Diseases*," by Dr. A. G. Signy; 5.15 p.m., "*The Radiological Diagnosis of the Rheumatic Diseases*," lantern lecture by Dr. Grace Batten.

Sunday

ST. STEPHEN'S HOSPITAL (RHEUMATISM UNIT), 369, Fulham Road, London, S.W.—October 2, 10 a.m., Ward Round with Demonstration of cases by Dr. Philip Ellman and medical registrars; 11.15 p.m., (1) "*The Non-Rheumatic Arthritides and Allied Lesions in General Medicine*," (2) '*Use and Abuse of Drugs in the Rheumatic Diseases*," lectures by Dr. Philip Ellman; 2 p.m., "*Orthopaedic Aspects of Rheumatic Disease and the Prevention and Treatment of Deformities*," by Mr. Timbrell Fisher; Demonstration of cases and treatment by manipulation (if cases are available), by Mr. Timbrell Fisher and medical registrars; 3.30 p.m., "*Radiotherapy in the Treatment of the Rheumatic Diseases*," by Dr. Jackson Richmond; 4.30 p.m., "*Pain—'Neuritic and Referred,'*" by Dr. C. Worster-Drought; 5.15 p.m., "*Psychogenic Rheumatism*," by Dr. David Shaw.

Monday

INSTITUTE OF LARYNGOLOGY AND OTOLOGY, 330, Gray's Inn Road, London, W.C.—October 3, 2.30 p.m., "*The Treatment of Facial Paralysis*," by Miss D. J. Collier.

Tuesday

CHADWICK TRUST.—At the Art Gallery, New Walk, Leicester, October 4, 4.30 p.m., "*Public Opinion and Public Health in the Age of Chadwick*," Chadwick Public Lecture by Mr. Asa Briggs.

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Postgraduate Medical School of London, Ducane Road, W., October 4, 3 p.m., "*Tuberculosis in Pregnancy*," by Dr. R. C. Cohen.

Wednesday

GLASGOW UNIVERSITY: DEPARTMENT OF OPHTHALMOLOGY.—October 5, 8 p.m., "*Biochemical Aspects of Methanol Poisoning*," by Dr. G. Leaf.

Thursday

FACULTY OF HOMOEOPATHY.—At Royal London Homoeopathic Hospital, Great Ormond Street, London, W.C., October 6, 5 p.m., "*The Place of Homoeopathy in Modern Medicine*," presidential address by Dr. Margery G. Blackie; "*Present State of Homoeopathy in America*," by Dr. Viola M. Frymann.

LONDON COUNTY MEDICAL SOCIETY.—At St. Andrew's Hospital, Bow, E., October 6, 3 p.m., clinical meeting.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Corner, London, S.W.—October 6, 4.30 p.m., lecture-demonstration: "*Neurology*," by Dr. A. Feiling.

Friday

KETTLE MEMORIAL TRUST.—At Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C., October 7, 5 p.m., "*The Significance of Functional Differentiation in Mammary Tumours*," Fifth Kettle Memorial Lecture by Dr. Beatrice Pullinger.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Benstead.—On September 16, 1949, at the Duke of York Home, Bradford, to Nancy Benstead, M.B., B.S., wife of J. G. Benstead, M.A., M.B., B.Chir., a daughter—Ursula Kathryn.

Holman.—On September 15, 1949, at Leeds, to Dorothy (née McNeill), wife of Dr. R. A. Holman, a son.

Lake.—On September 19, 1949, at "Fernwood," Newcastle-upon-Tyne, to Barbara (née Ivey), wife of Leonard H. Lake, M.B., B.S., D.O.M.S., 24, Eslington Terrace, Newcastle-upon-Tyne, a brother for Janet and John.

Leech.—On September 12, 1949, at Adrienne House, Axminster, Devon, to the wife of Dr. K. W. Leech, a son.

Waugh.—On September 16, 1949, in London, to Janet (née McDowall), wife of William Waugh, F.R.C.S., a daughter.

MARRIAGE

Backhouse—Izard.—On September 3, 1949, at the Christian Fellowship Centre, Honor Oak, London, S.E., Henry Lewis Backhouse, B.M.(Oxon), to Ruth Minifreda Izard.

DEATHS

Blair.—On September 20, 1949, at 5, St. John's Wood Road, London, N.W., George MacLellan Blair, M.B., Ch.B., aged 74.

Field.—On September 21, 1949, Arthur Holmes Field, L.R.C.P.&S.Ed., L.R.F.P.S., of Bridlington, Yorks, aged 82.

Fox.—On September 20, 1949, Joseph Tylor Fox, M.D., D.P.M., aged 64.

Fraser.—On September 22, 1949, at 29, Crownhill Park, Torquay, Frank Fraser, M.D., of Moorgate, North Bovey, and formerly of Leigh, near Tonbridge, aged 92.

Glanville.—On September 15, 1949, at Margate, Ruby Ellen Glanville, M.B., B.S., of "Everest," Longdon Wood, Keston, Kent.

Hewitt.—On September 21, 1949, at Muchlarnick, Pelynt, Looe, Edmund Philip Hewitt, L.R.C.P.&S.Ed., Lieutenant-Colonel R.A.M.C., Ret.

Sutcliffe.—On September 18, 1949, at Smitterfield, near Stratford-on-Avon, Percy Temple Sutcliffe, M.B., B.Ch.

Thomson.—On September 20, 1949, William George Simpson Thomson, M.B., Ch.B., D.P.H., D.P.M., of Cheadle Royal, Cheadle, Cheshire, aged 58.

Control of hypertension in advancing years

trade mark **'THEOGARDENAL'** brand

theobromine and phenobarbitone tablets

Combining the cardiac stimulant action of theobromine with the sedative effect of phenobarbitone, 'Theogardenal' is of particular value in alleviating the symptoms of hypertension, and especially in lessening the distressing effects of cerebral vascular changes. Middle-aged and elderly patients experience marked relief from giddiness, headache, loss of memory, and insomnia.

The drug has no cumulative effect and is well tolerated over lengthy periods.

Containers of 25, 100 and 500 tablets

(Each tablet contains theobromine gr. 5 and phenobarbitone gr. ½)

Our Medical Information Division will be pleased to send a copy of the medical booklet 'M&B Barbiturates in General Practice' on request

T.A.B., Cholera, and Smallpox Vaccination

Q.—*What is the youngest age at which T.A.B., cholera, and smallpox vaccines can be inoculated in a country like Pakistan or during an epidemic? What dosage should be employed? If it is considered that children under 1 year of age should not be inoculated, would you please give the reason?*

A.—Enteric fever and cholera are very rare infections in infancy, and young children who become infected usually have mild attacks. The inoculation of infants under 1 year of age with T.A.B. or cholera vaccines is therefore not recommended. For children of 1–5 years, one-quarter to one-third of the adult dose is given, and for older children half the adult dose. Smallpox can be a severe infection in infancy, and in a country where this disease is still prevalent the bulk of infection falls on children under 5 years of age. The newborn infant usually derives some passive immunity from the mother through the placenta, and the best time to vaccinate is between 2 and 6 months of age (optimum 3–4 months).

Sensitization to Actinic Light

Q.—*For the third summer in succession the skin of a woman aged 42 has reacted rapidly and severely on exposure to sunlight. The affected areas do not become tanned but remain pink, and subcutaneous nodules develop. The patient was in the Engadine in 1939 and was often exposed to strong sunlight, but there was then no reaction. Is there any reason for this late development of sensitivity? I would be grateful for advice on preventive measures and treatment.*

A.—The development of sensitization to actinic light may arise at any age and for no obvious reason; sometimes there is a familial tendency. At times, however, it is an accompaniment of metabolic changes associated with a focus of infection or gastro-intestinal dysfunction, or with endocrine imbalance as at the menopause. A careful overhaul and the correction of any fault would be wise. The taking of drugs, such as sulphonamides, may determine the onset. In idiopathic cases ephedrine or antihistamines by mouth, or injections of a gold salt in small dosage, may help. Protective applications are, however, generally necessary, and there are many effective ones, including *para*-aminobenzoic acid, yellow paraffin, titanium dioxide, tannic acid, quinine hydrochloride, and ichthyol powder. *Para*-aminobenzoic acid 15% in a cold cream or emulsifying base is suitable, or equal parts of "siccolam," yellow soft paraffin, and Halden's emulsifying base.

Infection of Seminal Vesicles

Q. *What is the best method of treating a gonorrhoeal infection of 20 years' standing in a man aged 60? The focus is believed to be in the seminal vesicles. Massage, sulphonamides, penicillin, vaccines, etc., have been ineffective. Would vasotomy and injection of seminal vesicles be likely to be successful?*

A.—It is probable that the infection is no longer gonococcal, but that the condition is now due to other organisms; it might be well to have any urethral discharge and prostato-vesicular secretion expressed by massage examined bacteriologically with special reference to *Trichomonas vaginalis* and pleuropneumonia-like organisms. It would be unwise to try vasotomy in a patient aged 60 unless his condition is serious, and it is by no means certain that any benefit would accrue. Unless a specific organism is incriminated it would be better to try short-wave diathermy applied to the prostate and vesicles every few days. Aureomycin is well worth a trial if available. It is possible, of course, that the focus is in the urethra; this can be confirmed or excluded by urethroscopic examination.

Effect of Alcohol and Tobacco on Fertility

Q.—*Would you please advise me of the investigations carried out on the effect of smoking and of alcohol on fertility?*

A.—Repeated intoxication with alcohol has been shown to have a deleterious effect on spermatogenesis in rats (C. Lane Roberts and others, *Sterility and Impaired Fertility*, Hamish Hamilton Medical Books, London, 1948, 2nd ed.), but the writer has not seen any account of experimental work dealing with nicotine. In view of the known damage caused, mainly to the testes, by certain bacterial toxins and chemical agents, it is not unreasonable to assume that chronic alcoholism and excessive smoking might lower fertility, and many writers mention it as a possibility without producing evidence to support it. If these conditions ever have such an effect, it is likely to be difficult to prove it, because in practice they can rarely be separated from associated factors which might also lower fertility. For instance, excessive smoking and drinking tend to occur in individuals who are overworked or exposed to severe mental stress or who are leading an unnatural and unhealthy life in other respects. Again, even if fertility is lowered the effect might not be directly due to the action of alcohol and nicotine on the gonads—it might be accounted for by poor appetite and malnutrition, which are prevalent among heavy smokers and alcoholics. It may be added that, although certain individuals may be susceptible, everyday observation makes it clear that fertility often continues unimpaired despite such excesses.

NOTES AND COMMENTS

Antiseptics for Minor Dressings.—Dr. Rupert Palmer (Lydd, Kent) writes: In an answer to a question on "Antiseptics for Minor Dressings" appearing in your "Any Questions?" column (September 17, p. 661) the statement is made that "mercury perchloride is not bland; it is exceedingly toxic and should never be applied to the body except, possibly, to the intact skin." This is complete and utter nonsense. The late Mr. Percy Legge, a senior honorary surgeon to King's College Hospital, under whom I was trained, used perchloride in varying strengths as a routine dressing for all his cases. I never saw one "go septic" or give any trouble whatsoever. I myself have used for the past twelve years a solution of 10% sodii sulphas in 1 in 2,000 perchloride as a routine wet dressing for all kinds of wounds large and small, skin abrasions, discharging boils, etc., with unvarying success. I have never seen any untoward sign at any time.

Corrections

Dr. Geoffrey Bourne (London, W.1) writes: Owing to a typing omission in my letter (September 24, p. 704) to you on distinction awards the point of my quotation from Pasteur has been missed. What Pasteur said was, "Tout le monde politique est contre moi." The occasion for this remark was his attempt to fight against the false dogma of spontaneous generation, and in this fight he was almost isolated in his opposition to the Académie Française and all it stood for in the way of subservience to tradition.

Mr. L. Fatti (Johannesburg) writes: May I draw attention to a small point arising in the article on "Direct Inspection of Coarctation of the Aorta with a Thoracoscope," by Mr. J. R. Belcher and Dr. F. E. de W. Caley (*Journal*, August 6, p. 137)? A personal communication is attributed to me dated 1949, stating that I had used this procedure before performing Blalock's operation. I think an error in the date has been made, since I left England in February, 1948, for South Africa. I performed the manœuvre first in 1947, and referred to it frequently before leaving England. Since then I have used it with increasing frequency for refining the diagnosis in various types of abnormality of the heart and great vessels, including coarctation of the aorta. The procedure is here becoming part of the diagnostic armamentarium of these diseases. Publication of the method has been delayed until a variety of cases has been accumulated to demonstrate its different aspects and uses.

Messrs. Butterworth and Co., Ltd., the publishers of *Modern Trends in Diagnostic Radiology*, which was reviewed in the *Journal* of September 24 (p. 688), write: Unfortunately the last paragraph in the excellent review is liable to give readers the impression that they will be unable to obtain a copy until the "second edition" is available. This is not the case. We are not doing a second edition yet, and the reviewer must be referring to the second printing.

In Dr. B. G. Gretton-Watson's communication (September 17, p. 651) the letters D.P.H. appeared instead of C.P.H.

All communications with regard to editorial business should be addressed to The Editor, British Medical Journal, B.M.A. House, Tavistock Square, London, W.C.1. Telephone: Euston 2111. Telegrams: *Aitiology, Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone. Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs.
ADVERTISEMENTS *should be addressed to* the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). Telephone: Euston 2111. Telegrams: *Britmedads, Westcent, London.*

SUPPLEMENT TO THE
BRITISH MEDICAL JOURNAL
LONDON SATURDAY OCTOBER 1 1949

THE SECRETARY REPORTS

SENIOR HOSPITAL MEDICAL OFFICERS

It was clear from the discussion at last week's meeting of the Central Consultants and Specialists Committee that, although the process of reassessment has resulted in a certain amount of upgrading, a substantial volume of dissatisfaction still remains. The problem falls into two main parts: the first, the satisfactory grading of existing hospital staffs, and the second, the question of new appointments to the senior hospital medical officer grade in the future. The committee was told of what the Joint Committee had done and was doing to press for a further professional central review of the cases of dissatisfied practitioners by a committee of practitioners not involved in the earlier assessment or reassessment.

On the second point the Ministry invited the Joint Committee to submit some words to define the circumstances in which new appointments should be made to the grade, and the Ministry is now considering the Joint Committee's proposed definition. On the point of central appeal—generally regarded as the most satisfactory way of dealing with the dissatisfaction which undoubtedly exists—an alternative might be to bring forward and now to conduct the review which the Ministry has promised for two years' time. Incidentally, the grievance is not limited to senior hospital medical officers, for there are some members of hospital staffs put into the grade "General Practitioner (b)" who are pressing for the reconsideration of their grading.

Medical Superintendents of Fever Hospitals

The council of the Society of Medical Officers of Health at its meeting on September 16 discussed one matter on which it is wished to promulgate its advice immediately. This was the grading of medical officers of health who are part-time medical superintendents of infectious-disease hospitals and of some whole-time medical superintendents. It was learnt that many such officers have been offered by regional hospital boards the grading of senior hospital medical officer, and that their appeals against this grading have been rejected. It is the view of the society that medical officers with specialized knowledge of infectious diseases should be graded as consultants.

It is understood that these medical officers are being asked to sign contracts as senior hospital medical officers by October 1. The advice of the council of the society is that they should refuse to sign such contract until the question of grading has been further negotiated, but at the same time intimate their willingness to continue duty until the matter is satisfactorily settled.

General-practitioner Remuneration

General practitioners may be wondering why no announcement was made following the visit of a deputation from the General Medical Services Committee to the Ministry on Friday, September 23. The reason is that the time was almost wholly occupied in a critical examination of the Ministry's statistical document on general-practitioner remuneration. As a result of the meeting the Ministry is reconsidering the document, which will in due course—and it is hoped in an amended form—be published.

It is clearly desirable that any document purporting to inform the public and the profession of the earnings of general practitioners should be above criticism and free from errors or wishful thinking. It is perhaps unfortunate, as the dentists have found, that there is a tendency to seize upon a high income received by a single practitioner and to give it such publicity as to suggest that this is the usual income. Perhaps general practitioners will be spared from such misleading influences if it is appreciated that as soon as lists are brought down to the legally permitted maxima it will not be possible for a practitioner to receive a gross remuneration in excess of a multiple of 4,000 and the capitation fee locally payable, plus relatively small sums in respect of midwifery, immunization, notification fees, and what private practice there is.

It is perhaps not generally appreciated that the moneys paid by local executive councils to practitioners may bear no relationship to the sums actually received by the practitioner after the partnership deed has been put into operation. Everything is being done to secure the Ministry's reply to the representations of the General Medical Services Committee before the Conference of Local Medical Committees on October 27.

Civil Service Medical Officers

A Joint Committee, representative of the British Medical Association, the Institution of Professional Civil Servants, and the Medical Staff Association of the Ministry of Health, has made a claim to the Treasury for improvements in Civil Service salaries. The Joint Committee claims that Civil Service medical officers' salaries should be aligned with the recommendations of the Spens Report. A meeting took place with the Treasury some days ago, when the Joint Committee elaborated its claim.

The claim is:

Medical Officer, General Service Class: £1,380 (at age 32) × £60—£1,560 × £120—£2,300.

Medical Officer, Linked Departmental Class. £1 660 (at age 35) × £120—£2,300.

Grades above the basic, General and Linked Departmental Classes: Grade I, £2,750; Grade II, £3,000; Grade III, £3.500.

Chief Medical Officer, Ministry of Health: £5.000

Deputy Chief Medical Officers for Department of Health for Scotland and Ministry of Pensions: £3,000.

Central Consultants and Specialists Committee

The question has been asked whether the Central Consultants and Specialists Committee is representative of those not graded as consultants and specialists as well as of consultants and specialists themselves. The position is that the committee is to represent the interests of senior hospital medical officers, registrars, and medical superintendents. A group of registrars is being formed which will give them representation on the Central Committee, and registrar members of the regional committees will be invited to appoint an additional representative.

In addition senior hospital medical officers will be included in the electorate for the election of regional consultants committees. There will be an election of these regional committees after the issue of permanent contracts. They will be advised to co-opt to their membership a medical superintendent where the ordinary processes of election have not resulted in one being elected; that teaching and non-teaching institutions should be adequately represented; and to co-opt at their discretion representatives of whole-time local authority medical officers and, through the local medical committee, representatives of the general practitioners in the area.

WELFARE OF AGED AND DISABLED

REGISTRATION AND INSPECTION OF HOMES

Further important measures under the National Assistance Act, 1948, designed to protect the welfare of aged and disabled persons are to come into force on November 1. An Order fixing this date for the coming into operation of the sections dealing with the registration and inspection of disabled and old persons' homes by county and county borough councils has been made by the Minister of Health, who has also made detailed regulations.[1]

The Minister has also named July 1, 1950, as the date on and after which persons carrying on a home that is unregistered render themselves liable to penalties. The purpose of this deferment is to give proprietors of existing homes ample time to apply for registration and to afford the registration authorities sufficient time for dealing with the applications. Homes to which the regulations apply are defined in the Act as establishments the sole or main object of which is, or is held to be, the provision of accommodation, whether for reward or not, for persons who are blind, deaf, or dumb, or are otherwise substantially and permanently handicapped by illness, injury, or congenital deformity, and for the aged, or both.

The Act specifically excludes hospitals maintained in pursuance of an Act of Parliament; institutions for persons of unsound mind or certified or approved under the Mental Deficiency Acts; nursing-homes as defined in the Public Health Act, 1936; any voluntary home as defined in the Children and Young Persons Act, 1933; and any premises managed by a Government Department or local authority or body constituted by special Act of Parliament or incorporated by Royal Charter. The Minister also has power to exempt premises from registration by regulation, and he has granted exemption to any establishment held upon a charitable trust which is an endowment within the jurisdiction of the Charity Commissioners, provided it was being carried on before November 1 and provided only accommodation and not board was supplied for the residents. The primary object of this exemption is to enable almshouses to be carried on for the time being without registration.

It is not known how many premises in England and Wales are liable for registration and inspection, but it is believed to be several thousand. Detailed instructions about the registers to be kept have been sent to county and county borough councils, who will prepare forms for completion by proprietors. Full information will be available shortly at county and county borough council offices, and all persons who feel that their premises may be liable for registration are advised to inquire at the appropriate council office.

The decision whether to register a home or not rests with the appropriate local authority, but the Minister is advised that the expression "any establishment the sole or main object of which is, or is held to be, the provision of accommodation" would not include a private residence where, in order to augment his income, a householder advertised his willingness to care for, say, an elderly or disabled person or married couple. He is further advised that the expression would not include premises which could clearly be shown to be houses or flats occupied or intended to be occupied as separate dwellings by aged or disabled persons.

Grounds on which the registration authorities can refuse or cancel a registration are set out in the Act. There is machinery for an appeal against a decision through a court of summary jurisdiction, and there are also provisions to allow for the inspection of the register by members of the public. The penalties laid down in the Act for carrying on an unregistered home are a fine not exceeding £50 in the case of a first offence and in the case of a second or subsequent offence imprisonment for a term not exceeding three months, or a fine not exceeding £50, or both.

[1] *National Assistance (Registration of Homes) Regulations*, 1949 (S.I. 1949, No. 1622), H.M. Stationery Office, price 1d. or post free 2d.

MEDICAL PRACTICES COMMITTEE REPORT

The Medical Practices Committee has issued the following list of amendments to its report (*Supplement*, August 6, p. 70):

Schedule 1

Glamorganshire.—Neath should read Neath Municipal Borough.

Schedule 2
Counties

ADDITIONS

Glamorganshire.—Bishopston and Reynoldston (Gower Rural District); Rhiwbina and Whitchurch (Cardiff Rural District).
Cumberland.—Longtown District.
Devon and Exeter.—Chudleigh; Bampton; Ivybridge; Silverton; Ide; Topsham; Elburton; Oreston; Plympton.
Cornwall.—Calstock; Gunnislake.

DELETIONS

Lincolnshire (Lindsey).—Scartho.
Suffolk (East).—Great Horkesley.
Sussex (West).—Petworth.
Yorkshire (North Riding).—Ripon.
Devon and Exeter.—South Molton; Calstock; Gunnislake; Crownhill.

CORRECTIONS

Worcestershire.—Stourbridge-on-Severn should read Stourport-on-Severn.
Glamorganshire.—Neath should read Neath Rural District.

Schedule 3
Counties

ADDITIONS

Sussex (West).—Petworth.
Devon and Exeter.—Cullompton; Kingsteignton; South Molton.

DELETION

Cumberland.—Silloth.

Schedule 4
Counties

ADDITIONS

Carmarthenshire.—Pontyates; Trimsaran.
Glamorganshire.—Dinas Powis; Radyr.
Cumberland.—Silloth.
Devon and Exeter.—Roborough; Sampford Peverell; Bere Alston; Chagford; Memyock; Ipplepen; Torrington (Great); Whimple; Lewdown.

DELETION

Devon and Exeter.—Chudleigh.

TRAVELLING EXPENSES OF PATIENTS' RELATIVES

The Minister of Health has had his attention drawn to instances in which near relatives of a patient in a hospital at a considerable distance from home have found it difficult to afford the cost of visiting the patient. In the Minister's view, according to a recent circular, it would be open to a local health authority, within the scope of its arrangements under Section 28 of the National Health Service Act, to provide travel warrants where it is satisfied (1) that because of the length of the journey the relatives concerned are unable to afford it from their own resources without substantial hardship, and (2) that there is urgent reason for the visit because of the patient's serious condition, or that the visit would in medical opinion do the patient good and aid response to treatment—for example, in the case of a long-stay tuberculosis patient too far from home to be readily visited.

The local health authority will normally need to rely on information from the hospital concerned that the visit is necessary or expedient on medical grounds. This circular has therefore been brought to the notice of boards of governors of teaching hospitals and hospital management committees with a request that they will ask their medical staff to assist local health authorities in this matter.

The Railway Executive has granted facilities for return journeys at single fare for persons visiting long-stay patients in certain institutions (such as sanatoria or mental hospitals but not general hospitals) who obtain in advance an authorized

voucher from the hospital concerned. This concession will not apply where a local health authority accepts liability for travelling expenses in pursuance of the present circular, but an authority will doubtless take into account the availability of the concession (in cases in which it may be obtained) in determining whether or not the cost of the journey is within the means of the person who seeks the authority's assistance.

REGISTRATION OF OPTICIANS

COMMITTEE TO INVESTIGATE

The Minister of Health and the Secretary of State for Scotland have appointed a committee to advise, on the assumption that it would be to the public interest that provision should be made by legislation for the registration of opticians, how registration could best be carried out and what qualifications should be required as a condition of registration.

The members are: Lord Crook (chairman); Mr. W. B. Barker, F.B.O.A.; Mr. G. W. Black, F.R.C.S.; Mr. R. Champness, LL.M.; Dr. J. Corlett, M.P.; Dr. Macdonald Critchley, F.R.C.P.; Dr. C. A. Lovatt Evans, F.R.S.; Mr. S. W. Gerrie, F.S.M.C.; Mr. G. H. Giles, F.B.O.A.; Mr. C. H. Keeler, F.A.D.O.; Dr. J. Marshall, F.R.F.P.S.; Mr. L. C. Martin, D.Sc.; Mr. O. Gayer Morgan, F.R.C.S.; and Mr. A. Shanks.

Lord Crook, who was honorary secretary of the Labour Parliamentary Association from 1945 to 1947, is a member of the National Whitley Council for the Civil Service and of the Ministry of Labour Departmental Whitley Council of London.

HEALTH SERVICE NOT TO BE TOUCHED

Mr. Bevan said he had made up his mind that the National Health Service was not going to be touched, "and there is no disposition by the Government to touch it," when he spoke on devaluation at a Labour rally at Hednesford, Staffordshire, on September 25 (*The Times*, September 26). The Government had made up its mind, he added, to solve its problems without raiding the social services, and the Health Service was sacrosanct.

SOME HEALTH SERVICE PAYMENTS

According to information given in a report of the Lothians and Peebles area (*Observer*, September 25), an optician was paid £14,077 in the first year of the National Health Service. The average payment to doctors in the council's area was £2,483; the average to dentists, apart from those with only branch surgeries, was £4,455. The 45 opticians received £56,147.

Questions Answered

Wife Acting as Nurse-receptionist

Q.—*I have been paying my wife £350 per annum salary for her duties as nurse-receptionist, etc., in my practice, and I have been deducting P.A.Y.E. contributions. In consequence I have been stamping her National Insurance card with 7s. Id. stamps each week, but have now been informed that a wife cannot be under contract as an employee of her husband, and that therefore neither Class I nor Class II contributions should be paid.*

A.—It is laid down in the National Insurance Act that in no circumstances can a wife be employed by her husband and thus become a Class I contributor. In the case of a wife acting as nurse-receptionist for her husband, she has the choice of contributing in Class II or Class III. (See S.I.1425. Pt. 3B section 21.)

Class II (Self-employed persons).—She must work for more than 24 hours a week. Her contribution is 5s. Id. per week and she qualifies for sickness benefit and for retirement pension at the full rate of 26 shillings per week at the age of 60.

Class III (Non-employed persons).—Her contribution is 3s. 8d. per week and she qualifies only for retirement pension at the full rate at the age of 60.

Partnership Agreement

Q.—*I would like to know the action to be taken for a partnership agreement to become officially valid and operative.*

A.—It should be presented to the Medical Practices Committee, Devonshire House, London, W.1, for perusal. The Committee will, if it is satisfied with the terms, issue a certificate of approval.

HEARD AT HEADQUARTERS

Quite a Phenomenon

Mr. John W. McPherrin, who is the editor of the *American Druggist*, recently toured this country in order to study the workings of the National Health Service. He was granted an interview by the Minister of Health and immediately afterwards he wrote an account of his talk with Mr. Bevan. His report appears in the July issue of the *American Druggist*, from which the following is quoted:

"'Most people trust their individual doctors,' began the Minister. 'At least they trust them more than they do organized medicine, the associations of doctors. When a doctor becomes a member of an organized group something seems to happen to his thinking. Did you ever notice that? It is quite a phenomenon.

"'The mental change that comes over a doctor when he functions as a member of organized medicine is unbelievable. It ought to be the subject of psychological research. You know that organized medicine has always been arrogant, always on the defensive. What are these doctors afraid of? Maybe they have an inferiority complex of some kind. It is all very surprising, because, as individuals, doctors—most of them—enjoy the faith and confidence of the public.' That was not all that the Minister had to say about doctors, but it's enough to give an impression of his attitude."

Length of Curriculum

The World Medical Association has been ascertaining the standards of medical education in various countries, and its latest *Bulletin* contains a mass of information on this subject. One point only may be mentioned here: the considerable variation in the length of the medical curriculum in different countries. It is five years in Austria and Hungary; five and a half years in Czechoslovakia; six years in Australia, Bulgaria, Eire, Greece, Italy, Luxemburg, and New Zealand; six and a half years in Switzerland; seven years in Belgium, Norway, and Spain; seven and a half years in Holland, and over eight years in Denmark. In Canada, Sweden, and the United States the medical course is four or five years in length, but must be preceded by pre-medical or pre-science education for three to four years.

WORLD MEDICAL ASSOCIATION

The General Assembly of the World Medical Association is meeting at B.M.A. House between October 10 and 16. During that week there will be some dislocation of the ordinary routine at B.M.A. House, particularly in the service of lunch in the Members' Common Room. Members wishing to take lunch during the W.M.A. Meeting are asked to do so as early as possible—i.e., between 12 and 1.

GENERAL MEDICAL SERVICES COMMITTEE

SUPPLEMENTARY REPORT, 1948–9

Remuneration

The committee regrets that it is not yet in a position to make a statement to local medical committees on remuneration. The Ministry's report on its survey of moneys received by general practitioners from National Health Service sources during the first nine months of the Service was received on August 18 and was considered by the committee on August 31. The Ministry's calculations are being challenged, but owing to the absence on leave of the Ministry's financial advisers concerned in the preparation of the tables it was not possible to arrange a meeting earlier than September 23. No time will be lost in issuing a statement to local medical committees as soon as the situation permits.

Mileage

The information collected as a result of the inquiry referred to in the committee's report has now been examined by the committee after a detailed analysis had been made by the Rural Practitioners' Subcommittee. The conclusion reached is that the global sum of £2 million is adequate for Great Britain as a whole, but that the figures reveal discrepancies in some areas which indicate that the distribution of the Fund is urgently in need of revision.

The Ministry of Health is at present engaged in collecting data to be used as the basis of future distribution of the Central Fund between executive councils. Every executive council concerned with the payment of mileage has been asked to classify the practices in its area and submit returns showing the number of mileage units claimed, calculated on a uniform basis of one unit for each mile or part of a mile beyond two miles from the doctor's residence to the patient's address. Classification of practices is effected by dividing the total number of persons on the doctor's list by the total number of mileage units credited to him. Should this calculation result in a figure of less than 0.75 the practice would be classified as (A) rural; if between 0.75 and 2.5 classification would be (B) semi-rural; and if over 2.5 it would be (C) urban. The number of ordinary units credited to Class B practices are to be increased in executive councils' returns by 50%, in Class A practices by 100%, while Class C practices will not be "loaded." The Central Fund will then be divided on the basis of these returns.

The General Medical Services Committee's view is that each area should be free to distribute its share of the Central Mileage Fund in accordance with the wishes of the local doctors, having in mind the committee's recommendation that the following method of "loading" units is considered to be equitable:

Urban practices: 1 unit for each mile or part of a mile beyond two miles from the doctor's residence.

Semi-rural practices: 1½ units for each mile or part of a mile beyond two miles from the doctor's residence.

Rural practices: 2 units for each mile or part of a mile beyond two miles from the doctor's residence.

It is being recommended, on the advice of the Rural Practitioners' Subcommittee, that in addition to ordinary mileage, when walking is necessary under winter conditions, additional units over and above the actual mileage should be claimed on the basis of one unit for each quarter of a mile walked. The "loading" resulting from the classification of practices into urban, semi-rural, and rural would not apply to the extra payments for "walking" units.

The problem of specially difficult areas, such as particularly mountainous districts and islands off the coast, has been given careful consideration, a certain amount of information having been obtained from the areas concerned. It is proposed to ask local medical committees to supply detailed information of practices containing peculiar difficulties or hazards, which it is considered should be divided into two categories: (1) individual cases of isolated patients where an *ad hoc* payment from the Mileage Fund should be suggested in each instance; (2) practices where a doctor generally is faced with unusual difficulties, and where it would be appropriate that help should be forthcoming from the Special Inducement Fund.

The committee's attention was drawn to certain criticisms made that there had been lack of consultation with local medical committees. The committee feels that it is necessary to point out that any apparent lack of consultation was conditioned by the need to take some positive and speedy action. The urgency of the mileage question was constantly being stressed by rural practitioners. It should be emphasized that the scheme which is ultimately adopted must be reviewed in the light of experience, when all local medical committees will be invited to comment upon it.

Inflation of Doctors' Lists

By way of an experiment the Ministry of Health has arranged for a few executive councils to send to a number of persons whose identity numbers are not known a communication asking for those numbers. The reply is being prepaid, and if the result of the experiment shows that a measure of inflation has been eliminated general action on the same lines will be considered.

List of Appliances

It has been decided to ask the Ministry to add the following to the list of appliances which general practitioners may order for their patients: ligature material; male and female urinals; "lastonet."

"Covering" an Unqualified Practitioner

A comparison of the certification requirements of the old and new regulations has been made and, generally speaking, the changes appear to be to the advantage of the doctor. On the point at issue—that of "covering" an unqualified person by issuing certificates when the patient is under treatment by such a person—the committee's legal advisers take the view that a doctor in the Service is required, under the regulations, to issue Ministry of National Insurance certificates even though he may know that the patient is receiving treatment from an unqualified person.

The certification rules under the N.H.I. Act specifically absolved a doctor from any obligation to give a certificate to a patient whilst he was obtaining treatment "from any other person or from any hospital or institution," unless the treatment was being obtained on the instructions or with the consent of the doctor or under Ministry of Pensions arrangements. The National Insurance Certification Regulations, which embody the rules governing certification under the new Service, do not contain a similar provision. Parallel with this, the old rules provided that certificates were to be given "by medical practitioners *who are attending* insured persons." The absence of these words from the present rules makes the doctor's position in the matter of "covering" more uncertain, and the committee is asking for similar words to be inserted in the present certification regulations.

Local Medical Committees—Travelling Expenses

The committee wishes it to be known that the decision to assist local medical committees in meeting claims for travelling expenses for members attending meetings of those committees is not limited to Scottish local medical committees. It is recognized that there may be committees in England and Wales which are experiencing difficulty in this matter, and the decision may be taken to apply to any committee in Great Britain.

Special Inducement Fund

In discussions with the Ministry of Health soon after the National Health Service was introduced it was understood that, whilst the main purpose of the Special Inducement Fund was to help doctors practising in sparsely populated or otherwise unattractive areas, sympathetic consideration would also be given to applications from doctors who had suffered considerable reductions in income as the result of the introduction of the Service. There is evidence that applications under this last

heading from practitioners in adequately doctored areas are being refused, despite the fact that they have the support of the local medical committee. The G.M.S. Committee is again pressing for a widening of the scope of the Special Inducement Fund so as to include definite cases of hardship irrespective of the type of area in which the doctor is practising. Representations are also being made against the Ministry's action in reducing a grant to a partnership, consisting of a husband and wife who are both engaged in and necessary to the Service, on the ground that they can normally manage on a smaller joint income than two doctors living independently. There is no indication that a similar reduction is being made in the case of father and son in partnership.

Medical Examination of Hospital Staff

The committee is informed that fees for the medical examination of candidates for appointments in the National Health Service are payable by the appointing authority, and an instruction to this effect has been issued to hospital management committees (Circular H.M.C. (42) 2). Although this instruction relates to administrative staff, some of the rulings given in it, including that relating to medical examinations on appointment, are of general application throughout the Service.

It is understood that the maximum fee which hospital authorities are permitted to pay is one guinea, but the committee is pressing for a fee of not less than 25s., as agreed in the case of other Government Departments.

Emergency Treatment—Police Authorities

The committee has approved the draft of a letter to be issued by the Home Office for the guidance of police authorities in connexion with emergencies involving the services of general practitioners. Briefly, the advice about to be given is as follows:

1. Apart from road accidents in which a motor vehicle is involved, for which a fee is payable under the Road Traffic Act, a doctor in the National Health Service who is called to an emergency would claim an emergency fee from the local executive council. If the doctor is not in the Service the police would pay the doctor's fee and recover it from the patient if possible.

2. Attendance on a person detained in custody or attendance for the examination of a person for police purposes (e.g., to see if he is fit to be detained in a police cell) would be paid for out of the police fund.

3. For examination of a victim of an offence in connexion with which a criminal charge may be made the fee would be paid from the police fund.

4. Attendance on a person taken ill near a police station and taken into the station while the doctor is summoned would constitute an emergency under the National Health Service, a claim being made to the local executive council for the payment of the appropriate emergency fee.

5. A doctor called in by the police to examine a man charged with drunkenness or any other offence would be paid out of the police fund. If the person wished to be examined by his own doctor he would be responsible for the doctor's fee.

6. A doctor called in to give treatment to a person and finding, on arrival, that the person is dead would be entitled to an emergency fee from the local executive council. If summoned, however, to confirm, for police purposes, that a body is dead, or to furnish a report as to the nature of the deceased's injuries, or to give an opinion as to the cause of death, the doctor's fee would be paid from the police fund.

Pension and Insurance Scheme

The Pension and Insurance Scheme which was available for insurance practitioners and other members of the B.M.A. until December last has been revised by agreement with the insurance companies concerned. Like its predecessor, the revised scheme provides for pension, for family provision, and for disability. Full details will shortly be obtainable from the Medical Insurance Agency at B.M.A. House, Tavistock Square, London, W.C.1.

A supplementary scheme has been evolved which is likely to be of particular interest to practitioners in the National Health Service who are anxious to make adequate provision for their dependants, as well as possibly to augment their pension at retirement. The details of this supplementary scheme are almost complete, and it is hoped that the terms can be announced at the conference.

There have been inquiries for a pension and disablement policy to cover staff employed by doctors (dispensers, secretaries, etc.), and consideration is being given to the possibility of devising such a policy.

CONSULTANTS AND SPECIALISTS COMMITTEE

A FIGHTING FUND FOR CONSULTANTS

On being unanimously re-elected to the chair of the Central Consultants and Specialists Committee at its meeting on September 22, Mr. R. L. Newell said that he hoped the new session would not be as strenuous as the last. Nevertheless, there was still much important business for negotiation with the Minister.

The first matter considered was the setting up of an independent defence fund for hospital consultants, similar to the defence trust of the General Medical Services Committee. It was agreed that the scope of the fund should be inclusive of hospital medical staffs—namely, consultants, senior hospital medical officers, registrars, and junior hospital medical officers. With regard to the last two classes it was felt to be appropriate that to a fund organized for hospital staffs future members of such staffs should contribute. The object of the fund was defined as to assist, either directly or through the British Medical Guild, in defraying the expenses incurred in organizing or taking any action to protect the interests of those within its scope.

Contributions should be deducted at source by boards of governors, regional hospital boards, and hospital management committees, in the same way as general practitioners' contributions to their fund are deducted by executive councils. The initial target was felt to be difficult to fix, but a contribution at the rate of £1 per £500 gross income derived from hospital appointments was suggested. It was pointed out that much of the defensive work which would fall to such a fund would be on behalf of such private practice as remained, and under this arrangement the consultant with most private practice and least hospital work would subscribe least. It was hoped that those who were doing well in private practice would make additional voluntary contributions.

The fund is to be administered by the members of the Central Consultants and Specialists Committee as trustees.

Regional Consultants and Specialists Committees

The composition of regional committees, which has hitherto varied considerably, came forward in connexion with the re-election of such committees on the issue of permanent contracts. It was emphasized that regional committees were autonomous and local conditions vary greatly, but it was decided to advise regional committees to observe the following principles: that membership should be based upon the representation of consultants and senior hospital medical officers in each hospital group or groups aggregated for the purpose, and that the teaching interest should be not less than one-fifth of the total membership. It was also proposed that representatives of whole-time local authority medical officers and of general practitioners be co-opted at the committee's discretion. It was felt that medical superintendents should be represented, and that if a medical superintendent did not find his way on to the committee by ordinary election a representative should be co-opted. The chairman said that these were only suggestions to the regions, and that regional freedom would make for a good committee.

Special Distinction Awards

The committee considered a letter which had been received by the British Medical Association from the Advisory Committee on Distinction Awards, which is now collecting evidence on which to base its recommendations, asking for any assistance which the Association was able to give. The Central Committee had formulated last December a number of conditions concerning these awards. It was urged that the Central Committee should seek to define "merit," and it was agreed to refer the matter back to the Executive Committee with a view to a

more comprehensive report embodying some ideas on the issue of "merit." One member observed that eventually "the only criterion of merit will be that a consultant has stuck to medicine or surgery for ten years!"

Senior Hospital Medical Officers

On the grading of hospital medical staffs, one member said that grave injustices were being done to men who had long been recognized as consultants but who were still, after appeal, graded as senior hospital medical officers. Dr. Rowland Hill, chairman of the Executive Committee, said that the Ministry had given an unqualified guarantee that it was not its intention that the grade of S.H.M.O. should become a cheap form of specialist service. It had gone further and stated that it would like the Joint Committee to advise on the future field for the S.H.M.O., and had, so to speak, left the ball in their hands. The Joint Committee had formulated certain principles governing appointments, one of which was that where the trainee system was in full operation—that is, in general hospitals where registrars were included in the establishment—there should not be any S.H.M.O. at all.

One Scottish member said that what was really wanted was the co-ordination of regions, which had been carried out in one part of the country with success. The central appeals machinery should be confined to the broader issues instead of dealing with a queue of aggrieved individuals.

Resolutions from the South-Western Regional Committee, including a recommendation that the S.H.M.O. grade should be provisional until the position had been clarified, were accepted by the committee.

Terms and Conditions of Service

Dr. Rowland Hill, for the Executive Committee, reported that that committee had considered a circular issued by the Ministry interpreting various points concerning the services of hospital medical and dental staffs. The provision that a consultant appointed before the age of 30 could proceed automatically from the initial salary of £1,400 was considered to be to the advantage of the officer. It was satisfactory to note that the duties expected under the liability to deputize for absent colleagues were to be taken into account in the pre-contract assessment. Certain anomalies concerning locumtenent arrangements were pointed out.

The Executive Committee brought forward for approval two model forms—for patients in "ceiling" and "non-ceiling" beds respectively—whereby the patient undertook to pay professional charges as a private hospital patient. Dr. Rowland Hill mentioned the unfairness of the position whereby a private patient who, because no private bed was immediately available, was admitted as an emergency for a few hours to a public bed and was thereby prevented from being treated as a private patient.

The committee endorsed a resolution from the South-Western Regional Consultants and Specialists Committee calling for pressure to be maintained to secure a grant-in-aid towards accommodation in pay-beds, the present costs being both prohibitive and likely to destroy private practice altogether.

GENERAL MEDICAL SERVICES SUB-COMMITTEE (SCOTLAND)

The advisability of recommending an extension of the use of the Inducement Fund in Scotland was debated by the General Medical Services Subcommittee (Scotland) at B.M.A. House, Edinburgh, on September 13. The chairman, Dr. Knox, said that of the £200,000 available, only £12,000 had been used up to March—£10,000 in Scotland and the remainder in England. The unexpended money returned to the pool, and the question arose therefore whether there should not be a wider use of the fund.

Dr. Jope pointed out that the small use so far made of the fund was, partly at any rate, explained by the fact that applications had been coming in late. Retrospective adjustment would be necessary. It was important that any widening of the scope of application should not adversely affect the use of the fund for its original purpose, which particularly applied to conditions in Scotland.

Dr. Wilkie Millar (Edinburgh) explained that the purpose of the Inducement Fund was to induce practitioners to go to those areas in which there was not a sufficient population and to provide them with a satisfactory income from capitation and mileage payment. It was also intended to induce practitioners to take up practice in less desirable city areas. There was no suggestion in the rules or regulations that it could be used to make up a financial loss resulting from the introduction of the National Health Service; fixed annual payments were intended for that purpose. They had heard from the Department officials that the Ministry were firmly of opinion that a practitioner could not draw on the fund for loss of income under the Act. This was probably a correct interpretation as things stood, but if any change of policy in the use of the fund was deemed desirable there was nothing to prevent representation being made to the Ministry and the Department that a change should be made.

Several members complained that there appeared to be no consistency in the method of allocating the fund. Dr. Wilkie Millar replied that the Department used a formula in assessing applications. In the case of rejected claims applicants had the right, provided they submitted figures in support of their appeal, to submit that the formula used by the Department was unsuitable to their case, and they should certainly do so.

Dr. Grant (Glasgow) reminded members that many practitioners in the cities had suffered greater hardship as a result of the National Health Service than those in the rural areas. In Glasgow the average net income of practitioners was about £800 per annum. He supported a suggestion that claims should be considered on the basis of the return made to the income-tax authorities in respect of income from practice.

In reply to a question as to what yardstick was applied to applications, Dr. Wilkie Millar said that, generally, income of less than £1,000 net per annum became entitled to a contribution from the fund.

Dr. Anderson observed that that might operate unfairly, no credit being given to the older man in respect of his years of experience and commitments.

Dr. Wilkie Millar said that a formula was necessary, but it might be that the Department formula was a wrong one.

On the suggestion of the Scottish Secretary it was agreed to ask the chairman's subcommittee to prepare a memorandum on the subject.

Filling Vacancies

The committee then considered means of speeding up the filling of medical practice vacancies. The matter arose in a communication to the Secretary of the Scottish Health Services Council from the clerk to Glasgow Executive Council, stating that his council was seriously perturbed at the length of time taken to fill a vacancy on the medical list. It was evident, he had said, that in a number of practices the numbers on the list of the deceased doctor had seriously diminished by the time a successor took over the practice. This was accentuated where there was an appeal, and the Glasgow Executive Council requested the Scottish Health Services Council to consider the possibility of abolishing the right of appeal by a practitioner against another succeeding to the practice in cases where the local medical committee, the executive council, and the Scottish Medical Practices Committee had agreed on the successor. The chairman observed that such a procedure, if adopted, would certainly speed up the position. It would, of course, need an amendment to the Act.

In reply to a statement that in Ayrshire a joint subcommittee had been formed of members of the local medical committee and the executive council in the hope of speeding matters up, Dr. Wilkie Millar pointed out that, while such a subcommittee might well be formed, it could act not in an executive but merely in an advisory capacity.

An opinion was expressed that in many cases delay occurred where a locum was an applicant, but it was pointed out that to stipulate that locums must not be applicants would be unfair and might lead to extreme difficulty in finding locums.

A motion to support the Glasgow Executive Council's proposal was defeated by 12 votes to 6 in favour of an amendment moved by Dr. Wilkie Millar that the selection of a candidate to fill a vacancy should lie with the executive council, advised by the local medical committee, with the right of appeal to the Medical Practices Committee.

The committee also agreed that canvassing by applicants should be a disqualification and that petitions organized by local residents should be firmly discouraged. It was further decided to recommend that there should be facilities for exchange of practices and that executive councils should be empowered to disperse or allocate practices of 500 or less.

Travelling Expenses

It was stated that the General Medical Services Committee had resolved that, subject to legal advice that it is within the objects of the National Insurance Defence Trust, the trustees be recommended to make a grant to a Scottish local medical committee applying for financial assistance towards the travelling expenses of its members in cases where such expenses, together with the other local medical committee expenses, are in excess of the income from an annual levy of 1d. per patient on doctors' lists in the area.

Other Business

The committee accepted the proposal of the Department of Health that in certain specified areas in the Highlands and Islands general medical practitioners should receive an appropriate fee from the Dental Fund in respect of emergency dental treatment carried out by them.

Other decisions made were to form a Colliery Practitioners' Subcommittee to consider and advise on matters affecting practitioners with relation to the coal and shale mining industries in Scotland in respect of problems peculiar to these industries; to take up with the Department the difficulty entailed in travelling in certain rural areas for the issue of weekly certificates, and means of reducing inflation of doctors' lists.

It was agreed to ask the Consultants and Specialists Committee (Scotland) to take up the case of Nairn Hospital, where certain staff changes introduced by the Northern Regional Hospital Board have resulted in the exclusion of a number of general practitioners from the hospital.

Addressing the Society of Chiropodists at Edinburgh on September 22, Sir George Henderson, Secretary of the Department of Health for Scotland, said that chiropody, as a profession, had first been organized in this country in 1912, and shortly after that the first school of chiropody had been opened in London. The second had been the Edinburgh one, opened in 1924. There were now twelve schools recognized by the society, and about 600 students were in training. The Secretary of State for Scotland and the Minister of Health had no option but to consider as soon as possible what standard, duration, and type of training should be laid down as a yardstick of proficiency and accepted as the hallmark of the right to practise in a national service. The Ministers had set up a series of committees to consider these matters in relation to all the various branches of auxiliary workers and to advise them. One of those committees concerned the profession of chiropody. It was intended that the committees should consider the questions before them objectively from the national point of view. The Chiropody Committee had already had several meetings and was considering written evidence. He hoped to have its report reasonably soon. The Department had given advice to regional hospital boards to make adequate arrangements for a chiropody service in association with the hospital and specialist services. They hoped to develop a chiropody service in connexion with health centres; in the Department's first experimental centre, about to be built at Sighthill, a room was being specially earmarked for chiropody. Chiropody was now, or was about to be, a recognized form of treatment at many hospitals where it was not previously provided. The provision made by a hospital board usually meant that treatment was given at the hospital itself. But it was contemplated that where necessary, if recommended by the specialist, it could be given in the patient's own home by the hospital staff, and in addition arrangements for the employment of private chiropodis's were not precluded. The Service had had a particularly good start in Scotland because of the willing co-operation of four of the voluntary foot hospitals. They had come into the Service on their own initiative, and that had enabled the regional boards to use their premises and staff instead of having to start from scratch.

Correspondence

Payments by Patients

SIR,—On August 27 *The Times* published a leading article on "The General Practitioner," and on August 30 the same newspaper printed a letter from a doctor suggesting that the cost of the National Health Service might be lessened if patients paid a small tax to the chemist for each prescription. These publications might usefully be considered in conjunction with the statements made by the Ministry of Health in reply to the General Medical Services Committee on the subject of remuneration to general practitioners.

This vexed problem seems no nearer a solution. At a recent meeting of a local medical committee which I attended the view was expressed that it would be difficult to secure unanimity of action in any attempt to bring pressure upon the Minister to agree to an increased capitation fee. There has perhaps been insufficient recognition of the fact that the effect of the Act upon practitioners' incomes has been very unequal. It seems likely that some doctors are better off than before; it is equally certain that many have suffered loss. It is contrary to human nature for the former to take action in support of the latter, and thereby risk economic distress because of a dispute.

Doctors in some industrial and urban districts have not suffered financially if they have large lists. The recent increase in mileage allowance has improved the finances of practitioners in certain rural districts which are scantily populated and where patients live at great distances from their doctors; some of these are no worse—or even better—off than formerly. It pays them to have patients scattered over very wide areas; but their lives are harassed and their leisure practically *nil*. In one such district I know of, two doctors are engaged in their communal surgery for 3 to 3½ hours every morning, and then spend the whole day until nightfall on visits, taking a sandwich lunch in their cars and having no tea. This sort of life throughout the year is a poor return for an undiminished income.

The semi-rural practice, or country districts in which the bulk of the population live not more than two miles from the surgery, is in a different position. Their lists are limited by a comparatively small population, and the proportion of patients for whom mileage can be claimed is relatively small. There is no scope for increasing lists and incomes. Thus for most of their work they receive the minimum capitation payment, as does the town practitioner, but there simply are not enough residents to provide a similar income, while they have time-consuming long-distance work for a relatively small number of patients. In these districts the State practice is still subsidized by what remains of private practice. In one such practice, for example, if the whole of the population attended were State patients the gross receipts would now be only 60% of pre-1948 figures. Doubtless many such examples could be given.

The effect on these practices is not so much the loss sustained in the first year of the Service, but what it will become in the future. A certain proportion of elderly patients have remained private, but they are a steadily diminishing factor. Each quarter shows an increase in State lists and a smaller private list, and the fall in income from private patients is greater than the increase in executive council payments. This constitutes the greatest danger for many practices, to which, if we are to be fair, the Ministry's attention should be drawn. In a comparatively short time private practice in the country will be dead, and the income of the country doctor permanently lowered as we approach the 100% State practice. The loaded capitation fee thus seems to be the only reasonable assistance for the country or semi-rural practitioners.

On the other hand the economic situation provides a strong argument against any increased payments to doctors. But it is generally accepted that the Service is being grossly abused by increasing demands for attendances and the various additional benefits. It is obvious that the majority of patients could afford some contribution towards the cost of spectacles, dentures, and, in some cases, surgical appliances, as they did under the old N.H.I. Acts. If such a charge (e.g., £1 for a pair of spectacles

Is there any other section of the community in our Welfare State which remains on duty without overtime in order that patients may consult the doctor after their normal working hours? Is it consistent with the dignity of our profession that a patient should inform us that he desires this or that medicament and that if we refuse him he is able immediately to transfer his card and that of his family to a more accommodating doctor next door? Is it likely that sound and honest certification will be maintained with the system of immediate transfer, when the maintenance of a doctor's income depends on the kindliness of his certification?

I do not consider that the terms offered to our consultant colleagues are yet satisfactory, but none the less the relative values placed by the Ministry of Health on the two sections of the profession give food for serious thought. The consultant now receives reasonable remuneration for his hospital work, and in addition a fee of four guineas is granted for a domiciliary visit. It is estimated that a panel patient receives an average of seven services per year, which rates the practitioner's worth at about 2s. 6d. per service.

In the future I very much fear that general practice will be the field of the mediocre and unambitious and that only those will enter it who have failed to secure a preferable post in other spheres of medicine. In the past the good general practitioner felt himself pre-eminent in his own sphere and would not change his chosen vocation for any other branch of medicine. Under present conditions I cannot see that pride of place remaining.—I am, etc.,

Glasgow. IAN D. GRANT.

Insurance Contributions

SIR,—I read with interest the question entitled "Hospital Residents' Insurance Contributions" ("Questions Answered," *Supplement*, September 10, p. 132). I presume the ruling with regard to hospital residents applies equally to locums and public health employees temporarily unemployed.

As I understand your answer, an employed person who fulfils the requirements mentioned is exempt from payment of contributions, and is credited with one if he is capable of and available for work. Refusal to take work offered does not affect this. Also, he may draw unemployment benefit if he attends as instructed at the labour exchange. This is affected by his refusal to accept suitable employment. Can you say what is accepted as "suitable employment"?

I remember asking these questions when I first got my insurance card at the local labour exchange, and receiving the impression that, should I have the temerity to claim unemployment benefit, I would be offered a domestic or similar job at once, and if I failed to accept it would lose benefit and contribution.—I am, etc.,

Redcar, Yorks. MARGARET O. WILL.

Hypertrophy of the Appendix

SIR,—Dr. K. V. Deakin's statement (*Supplement*, August 27, p. 117) is, though not new, courageous and therefore most remarkable; for the facts mentioned are supposed to be common knowledge within the profession. What, however, the bulk of our profession does not perhaps realize is that practically everything attributed in the letter to the dental profession may as well apply, in one way or another, to all auxiliaries attached actively or passively to the medical profession in this country—i.e., from the dentist via the electrotherapeutist, nurse, hair-restorer, Indian eyesight restorer, health practitioner, chemist, herbalist, bone-setter, optician, ophthalmic optician, masseur, etc., etc.

They are all doing financially very well indeed with or without nationalization! No medical community in the world, perhaps with one or two exceptions, is faced with such an enormous army of auxiliaries created by the medical profession—*cui bono?*—and meant originally as an appendix to the profession. But I am sorry to say that few members of the profession do realize that the auxiliaries are no longer the appendix, as the medical profession is in imminent danger of becoming the appendix to the auxiliaries.—I am, etc.,

Accrington, Lancs. J. KATZ.

Inflation and Deflation

SIR,—In your note on inflation of doctors' lists (*Supplement*, August 27, p. 102) you make no mention of deflation of doctors' lists. To one who tries to be conscientious in keeping clinical records it is annoying to have to wait many months before medical history envelopes are received from executive councils. I recently sent a request to the executive council for all outstanding records of patients registering with me since July 5, 1948. (I keep a record of all Forms E.C.1 and E.C.4 which I sign.) Some records were outstanding for over a year.

The reply was disappointing. In some cases there was "*no* trace of this patient on the council's register." In others the patient was said to be "on the list of another doctor"; one such case was that of an infant whom I had delivered and whose parents had registered him with me only. I had treated all these patients, some for many months. We seem to have here an example of deflation of a doctor's list.—I am, etc.,

Torrington, N. Devon. C. F. R. BRIGGS.

His Own Doctor

SIR,—I should like to support Dr. A. D. Belilios's letter (*Supplement*, July 30, p. 68) in which he claims that doctors should have the right to prescribe for themselves. When the scheme came into force the Ministry of Health made great play that at no time would patients be directed to doctors. Surely this new regulation contradicts Mr. Bevan's statement.

As far as I am aware there is no ethical ruling that a doctor may not prescribe for himself. Why, then, should the Ministry decide otherwise? Perhaps, if this regulation is not resisted, it may mean the thin end of the wedge and very shortly doctors will be instructed what patients they should or should not have on their lists.

I think the medical profession as a whole should take a strong stand, otherwise who knows what may happen?—I am, etc.,

London, S.E.6. R. WIGODER.

Doctors and Dentists

SIR,—May I hasten to express to our dental correspondents (*Supplement*, September 10, p. 132) my regrets if I have in any way offended their susceptibilities. I hold the sister profession in high regard and agree whole-heartedly that the spirit of concord between the two professions is very desirable. I am in no way critical of the State payments to the dental profession. As they are the main beneficiaries of the scheme, I merely used their figures as a yardstick when comparing the payments to the doctors, and I was only quoting average payments, not individual. I was writing quite impersonally.

And yet in the midst of all this adverse criticism, in this their era of affluence, I failed to note one word of sympathetic reference in the dental criticism to the unfortunate position in which the medical profession finds itself to-day. In the Bolton figures recently published payments were: 50 dentists received £137,898=£2,760 average per annum; 35 ophthalmic practitioners and opticians received £72,795=£2,085 per annum: 55 chemists received £94,602=£1,720 per annum; and 106 doctors received £137,518=£1,301 per annum. The dentists and chemists would, of course, in addition derive considerable financial gain from their private practice. Medical private practice is, of course, practically eliminated.

These figures are more favourable to the doctors than the Manchester figures, which were: dentists, £3,400 per annum: doctors, £1,280 per annum. And yet 50 dentists are sharing more among themselves than 106 doctors, and are receiving individually over twice as much. Do our dental colleagues really believe that the doctors are adequately paid?

When the B.M.A. approach the Government with a plea for an increase of remuneration they are informed that there is no justification for an increase. It is apparently the policy of the powers that be, having got us down, to keep us down. How would our dental friends like to be in our shoes? Would they like to change places? Evidently we chose the wrong profession.—I am, etc.,

Manchester. K. V. DEAKIN.

Experiences of General Practice

SIR,—The practice, a partnership in an industrial town of 10,000 population and extending into country, covers an area of some 10 miles by 6 miles with an additional 5,000-odd rural population. There are seven doctors (in the town), of whom one is an assistant.

The whole population are N.H.S. units. The practice has 3,300 N.H.S. units, the writer's share being 1,600-odd units (i.e., 50% partnership). His total remuneration promises to be about £1,700. The figure embraces payments under N.H.S., including mileage, midwifery, life assurance examinations, Civil Service examinations, and salaries from hospital and clinic appointments.

During the summer and autumn months he has been seeing 60 patients per day (visits and consultations, approximately equal numbers) except on Sundays, when six is an average. Without taking peak periods into account this means 18,000 contacts per year, or a frequency of between 11 and 12 per patient. A similar amount of work in private practice would earn the writer about £4,500.

His average working day is 9 a.m. to 9 p.m. He manages to attend his meals with reasonable regularity, but, as is inevitable, there are additional emergency calls during the night, but not an unreasonable number.

Before the advent of the N.H.S. his gross earnings were about twice the amount quoted, £3,400, but in those days he provided a wide range of medical services now largely delegated to specialists. Nevertheless he is busier than in the old days.

His general deductions are that in the area every type of free facility is too fully utilized and often exploited. Sick workers are in no hurry to return to work, especially single ones (of both sexes). The injured are too "compensation conscious" and therefore difficult to rehabilitate. There is an extravagant use of medicines, dressings, and appliances. Any attempt on the part of the writer to counter these tendencies provokes the rejoinder, "If you don't, there are plenty of other doctors who will gladly," etc.

The overall tendency is therefore to reduce the standard of general practice to that prevailing in the large industrial practices. He finds it difficult to believe that under present conditions any doctor responsible for the medical care of over 2,000 units can maintain a high standard of practice.

Lest anyone might imagine that the writer lacks wide and varied experience, he gives the following data: G.P. experience 27 years—10 in England (large cities and rural), 10 years' "high-class practice," seven years in the present area. He is forced to the conclusion that the present system of remuneration is not conducive to the happiest results—i.e., uniform capitation irrespective of numbers or experience. Rising costs are inevitable as long as the doctor who refuses to acquiesce in the all-round exploitation does so at the risk of losing his practice and his living.—I am, etc.,

M.D.

Refusal of Partnership

SIR,—I hope that the leaders of our profession do not dismiss lightly letters written to the *British Medical Journal* by aggrieved experienced assistants. My own experience tallies with what has been recently written. Many principals, I am sure, are considerate employers, but that does not dispose of the underlying injustice whereby they are allowed to get a large amount of their work done by assistants at a relatively low cost to themselves. The end of buying and selling of practices is not the fault of assistants, and compensation will eventually be paid to principals. How, then, can the practice of making considerable profit out of an experienced assistant's work be justified? It implies that a principal can be twice paid for the loss of his goodwill. While such a loophole is legally permitted, junior partnerships will be scarce indeed.

The experienced assistant has no redress whatever if a principal for any or no reason at all refuses to offer the partnership which originally he held out as a goal to attract the best type of assistant. Dissatisfaction with the assistant's work is not by any means the sole reason for such a refusal, and often it is not a factor at all.

To become a principal other than through an assistantship-with-view is very difficult for the man without capital, and the B.M.A. is well aware of that but seems quite uninterested. Surely the B.M.A. represents all sections of the medical community, and if one section has, or even feels it has, a deep grievance it is the duty of the B.M.A. fearlessly to investigate that grievance. Refusal to do so will only lead to a grave lack of confidence in our Association, disunity in the profession, and finally a direct appeal to the Minister as the last hope of an ignored and unprivileged minority.—I am, etc.,

EXPERIENCED ASSISTANT.

Glasses in Three Weeks

SIR,—May I explain to Dr. Hardie what was in my mind when I wrote the letter published in the *Supplement* of August 27 (p. 119)? Perhaps I did not make myself clear.

The National Health Service promised a complete service to the poor. In this case a woman of quite limited means, who could not wait the stated 6–9 months for spectacles, had to pay £5 to obtain them in three weeks. Is there not something iniquitous in this? Let those who have the means buy anything they can, but a Government should not hold out hopes to the people which cannot be fulfilled. Does this latter not savour of vote-catching?—I am, etc.,

London, N.W.11. L. S. WOOLF.

Enforce Obedience

SIR,—It has been noted by many that the comradeship among general practitioners which developed at the time of the formulation of the Health Act has been cooling off. We seem to be slipping into the old ways and the old antagonisms. The handicap of this is that combined action is impossible, and we are now at the mercy of the interpreters of the Health Act and the formulators of its regulations. We can justly envy the tradesmen and artisans who are directed by their unions as to what to do and when to do it, with penalties against defectors.

It is time that our Association took upon itself the *right to enforce obedience*, time that we put medical policy on a national basis and authoritatively directed it. Then this fear that every one of us has that the black sheep will break up an agreed policy and ruin our chances of bettering our position will be dispelled.

When I brought up this matter at our local Divisional meeting it was suggested that the authority would grow to a tyranny. But surely in a democratically elected body this would never happen. There seems to be little tyranny in the artisans' trade unions.

However much we may yearn (to take three small instances) for less than a 24-hour day, for the confidence to refuse some certificates, or for more than a 4s. fee for a vaccination and inspection, we can do nothing to help ourselves so long as 10 or 20% of our number is satisfied (often because they happen to be more favourably placed financially) and cannot be compelled to follow the wishes of the majority.—I am, etc.,

Dungannon. CONN MCCLUSKEY.

N.H.S. Pros and Cons

SIR,—No doubt a flood of correspondence will appear in answer to Dr. J. S. Zidel's letter (*Supplement*, September 17, p. 138), its volume only limited by the lack of leisure between morning and evening surgeries. He has been lucky in his experiences of the N.H.S. and is to be congratulated on the numerous advantages over free general practice which he has noted. These advantages, however, are not clearly seen by many practitioners with whom I have discussed the Service, and I may be allowed to tabulate the answers to Dr. Zidel's list.

(1) Income may be secure—it would not be wise to be too sanguine on that point—but the doctors are certainly in the minority in the community in accepting more work for less pay.

(2) Expenses are not reduced in proportion to the reduction of income, and it is certainly necessary to have some form of clerical assistance if one is to preserve order in one's cards.

(3) Visits are more in number, and 60 miles a day is not at all out of the way for a country G.P. A single night call may involve 15–20 miles.

(4) Hours are certainly regular—perhaps 16 daily. Objection is made on the score of quantity, not regularity.

(5) One *is* harassed. Patients who were among the first to complete form E.C.1 are often too busy, or too snobbish, to attend as ordinary "surgery" patients, and want to use up a few minutes of that leisure between morning and evening surgery which Dr. Zidel has been so lucky in finding and which most of us find hardly adequate even for meals.

With all due respect to a visiting colleague, one can only assume that he saw all the good and none of the difficulties of N.H.S. practice. There has hardly been any of the summer falling-off in the work this year, and one hesitates to think of the volume of work which will come our way in the winter. The solution is easily written—more pay, more doctors. The difficulties have arisen simply because the Service was forced into being without due preparation, and surely the Minister of Health should be the first to realize that it is essential to lay the foundations and build the walls before putting on the roof.

However, we have our glorious Service, but, please, Dr. Zidel, don't tell us how lucky we are to be in this plight.—I am, etc.,

Spilsby, Lincs. C. E. FRISKNEY.

POINTS FROM LETTERS

A Medical Trade Union

Dr. W. WATSON NEWTON (Birmingham) writes: I warn all doctors that a medical trade union will bring all doctors within the control of one central organization which in its turn might, like so many other unions at home and abroad, be brought under political control for purposes far beyond the alleged benefit of practising doctors. I would advise all doctors to support the B.M.A.

Heading the Poll

Dr. LESLIE HARTLEY (Camberley, Surrey) writes: Socialists and Tories alike have claimed the credit for the success of our magnificent Health Service, at once the envy and admiration of every foreigner, but is not the credit really due to the Whigs?

Permanent Assistant

Dr. M. writes: . . . Many practitioners are now faced with doing assistants' jobs for many years—a grim prospect. But, since the profession has given up its freedom, even if an assistant is lucky enough to get a practice through the local executive council the chances are that the doctor has to live in some district in which prior to the scheme he would never have thought of settling. Again, if for family or health reasons he wants to move, he can't do so. . . . The outlook is certainly alarming for the young man, and while we hear that there are more doctors needed to work the scheme I fail to see why so many practitioners are doomed to an assistant's life, but it is so. . . .

H.M. Forces Appointments

REGULAR ARMY: EMERGENCY COMMISSIONS

ROYAL ARMY MEDICAL CORPS

Captain (now Major) W. S. Angus (now Regular Short Service Type "B"), to be Major.

Captain I. A. Jackson, M.B.E., to be Major.

Captain R. E. N. Tattersall has relinquished his commission, and has been granted the honorary rank of Major.

War Substantive Captains J. G. Guest and S. Graham have relinquished their commissions, and have been granted the honorary rank of Major.

COLONIAL MEDICAL SERVICE

The following appointments have been announced: F. C. Harris, M.R.C.S., and D. A. W. Nugent, M.D., D.P.H., Medical Officers, Gold Coast; Mrs. V. F. Wilkins, M.B., Lady Medical Officer, Nigeria; M. B. Wingate, M.B., Medical Officer, Northern Rhodesia; E. Gemmell, M.B., D.T.M.&H., Lady Medical Officer, Sarawak; K. N. H. Low, M.B., Medical Officer, British Guiana; W. J. M. Evans, M.B., D.P.H., Senior Medical Officer, Tanganyika; A. J. Johnson, M.B., D.T.M.&H., Senior Medical Officer, Sierra Leone; E. H. Murcott, M.D., D.P.H., Senior Medical Officer, Kenya; J. H. Taylor, M.B., Medical Officer, Kenya; G. Haridas, M.R.C.P., Physician, Government Hospital, Federation of Malaya; C. Subiahmanyam, Senior Pathologist, Federation of Malaya.

Association Notices

SIR CHARLES HASTINGS CLINICAL PRIZE

The Sir Charles Hastings Clinical Prize, which consists of a certificate and a money award of 50 guineas, is again open for competition. The following are the regulations governing the award:

1. The prize is established by the Council of the British Medical Association for the promotion of systematic observation, research, and record in general practice.

2. Any member of the Association who is engaged in general practice is eligible to compete for the prize.

3. The work submitted must include personal observations and experiences collected by the candidate in general practice, and a high order of excellence will be required. If no essay entered is of sufficient merit no award will be made. It is to be noted that candidates in their entries should confine their attention to their own observations in practice rather than to comments on previously published work on the subject, though reference to current literature should not be omitted when it bears directly on their results, their interpretations, and their conclusions.

4. Essays, or whatever form the candidate desires his work to take, must be sent to the British Medical Association House, Tavistock Square, London, W.C.1, not later than December 31, 1949. The prize will be awarded at the Annual General Meeting of the Association to be held in 1950.

5. No study or essay that has been published in the medical press or elsewhere will be considered eligible for the prize, and a contribution offered in one year cannot be accepted in any subsequent year unless it includes evidence of further work. A prizewinner in any year is not eligible for a second award of the prize.

6. If any question arises in reference to the eligibility of the candidate or the admissibility of his or her essay the decision of the Council on any such point shall be final.

7. Preliminary notice of entry for this competition is required, on a form to be obtained from the Secretary.

8. Each essay must be typewritten or printed, must be distinguished by a motto, and must be accompanied by a sealed envelope marked with the same motto and enclosing the candidate's name and address.

9. The writer of the essay to whom the prize is awarded may, on the initiative of the Science Committee, be requested to prepare a paper on the subject for publication in the *British Medical Journal* or for presentation to the appropriate Section of the Annual Meeting of the Association.

10. Inquiries relative to the prize should be addressed to the Secretary.

Diary of Central Meetings

OCTOBER

4	Tues.	Committee on Relationship of Autonomous Bodies, 2 p.m.
5	Wed.	Joint Committee of British Medical Association and National Veterinary Medical Association, 2.30 p.m.
14	Fri.	Committee on Industrial Health Services in relation to the National Health Service, 2 p.m.
18	Tues.	Proprietary Medicines Committee, 11 a.m.
19	Wed.	Film Committee, 2.30 p.m.

NOVEMBER

3	Thurs.	Committee on Industrial Health Services in relation to the National Health Service, 2 p.m.

Branch and Division Meetings to be Held

BOURNEMOUTH DIVISION.—At Royal Victoria Hospital, Boscombe, Friday, October 7, 8.15 p.m. Dr. Raymond Greene: "Vulgar Errors in Endocrinology."

EAST HERTS DIVISION.—At County Hospital, Hertford, Thursday, October 6, 8.45 p.m. Inaugural address by Dr. D. W. James: "The General Practitioner and the Maternity Service." The address will be followed by opportunity for questions and discussion.

GOOLE AND SELBY DIVISION.—At The Lodge, Snaith, Thursday, October 6, 8.15 p.m. Discussion on "Some Problems of Child Health," to be opened by Dr. Walter Henderson. Preceded by supper at 7.30 p.m.

RICHMOND DIVISION.—At Station Hotel, Richmond, Friday, October 7, 9 p.m. Dr. Gerald Slot: "On Angina Pectoris." Preceded by dinner at 7.45 for 8 p.m.

SWANSEA DIVISION.—At Morriston Hospital, Swansea, Thursday, October 6, 7.30 p.m., opening meeting. Address by Mr. C. J. Cellan-Jones: "The Atom Bomb and Us."

BRITISH MEDICAL JOURNAL

LONDON SATURDAY OCTOBER 8 1949

FAT METABOLISM AND THE SPRUE SYNDROME*

BY

A. C. FRAZER, M.D., D.Sc., M.R.C.P.

Professor of Pharmacology, University of Birmingham

The sprue syndrome is characterized by a defect of fat absorption, commonly associated with diarrhoea, wasting, abdominal distension, the radiographic segmentation pattern of the small intestine, absence of the normal post-absorptive systemic hyperlipaemia, a flattened oral glucose-tolerance curve, anaemia, and certain vitamin deficiencies. Defective fat absorption may be regarded as an essential part of the sprue system by definition. The sprue syndrome may be taken to include non-tropical sprue (idiopathic steatorrhoea) (Thaysen, 1932), tropical sprue (Fairley, 1936), and the coeliac syndrome in children (Parsons, 1932). To these may perhaps be added some cases of gastro-colic fistula. Other cases of defective fat absorption (such as the post-gastrectomy syndrome, regional ileitis, chronic pancreatitis, or obstructive jaundice) are not usually associated with a sufficient number of the characteristic features of the sprue syndrome to warrant their inclusion in this group (see Table I).

Tropical sprue can occur in epidemic outbreaks involving groups of people living under similar environmental conditions—this was often observed during the last war in South-east Asia—non-tropical sprue and the coeliac syndrome, however, occur more or less sporadically, although several cases may occur in one family. With tropical sprue recovery is the rule; with non-tropical sprue and the coeliac syndrome complete recovery is relatively rare. The syndrome in its more chronic form can be divided into two main parts—a more or less constant group of signs and symptoms, including the fat-absorption defect, and a more variable element, subject to exacerbations from time to time, including severe diarrhoea with bulky fermenting stools, vitamin-B deficiencies, and haematological changes

TABLE I.—*Features of the Sprue Syndrome*

	Coeliac Syndrome	Non-tropical Sprue	Tropical Sprue	Gastro-colic Fistula	Post-gastrectomy Syndrome	Regional Ileitis	Obstructive Jaundice	Chronic Pancreatitis

Signs of vitamin-B deficiencies	++	++	++	++	++	+	—	+

+++ Usually present. ++ Commonly present. + May be present. — Usually not present.

Certain differences can be observed between non-tropical and tropical sprue and the coeliac syndrome. The anaemia in the coeliac syndrome is usually microcytic, probably due to iron deficiency; an iron-deficient component is also commonly observed in the adult macrocytic anaemia. There may be several primary aetiological factors which can give rise to the sprue syndrome, and it is probable that different factors are operative in the three varieties of the syndrome under consideration.

*Read in opening a discussion at a joint meeting of the Sections of Pathology and Bacteriology and of Tropical Medicine at the Annual Meeting of the British Medical Association, Harrogate, 1949.

The Fat-absorption Defect in the Sprue Syndrome

1. Normal Fat Absorption in Man

Absorption from the intestine is conveniently considered in three phases: an intraluminar, a cellular, and a distributive phase. The absorption of fat must be studied both from a general point of view and in detail (Frazer, 1947a).

General Aspects of Fat Absorption.—The quantity of fat absorbed must be determined by the use of a fat-balance technique (Cooke *et al.*, 1946). More recently the method of de Kamer, Huinick, and Weyers (1949) has been successfully used. The criticisms of Annegers, Boutwell, and Ivy (1948) are not valid with regard to the use of these balance techniques for studies of defective fat absorption. The amount of fat ingested may be increased from 50 to 100 g. and the effect of this fat-loading of the diet determined quantitatively. The effect of different types of dietary fat can also be studied. In

addition to quantitative measurements, the characteristics of the faecal fat and the quantity of volatile short-chain fatty acids can also be determined. The results of observations made by these various methods in normal subjects are shown in Table II.

TABLE II.—*General Study of Fat Absorption*

	Normal	Sprue Syndrome
Fat-balance technique 5–12 day balance .. .. Daily fatty acid (de Kamer, 1949).. ..	> 95%	50–80%
Fat-loading tests 50 to 100 g.	Proportionate, 48–95 g.	Proportionate, 35–70 g.
Fat-assimilation test ..	Natural fats absorbed	Intolerance of saturated fats
Faecal fats	< 3 g. in 24 hr.	Neutral fat and fatty acid +++; 10–50 g. in 24 hr. High M.Wt. and M.P., low I.V.
	< 2 g. per 100 g. dried faeces	Volatile fatty acid +++ up to 8 g. per 100 g. dried faeces

Detailed Study of Fat Absorption.—The intraluminar phase of fat absorption can be studied by an intestinal intubation technique (Thompson, 1949). A Miller–Abbott tube is passed into the small intestine and samples of intestinal contents taken before and after the administration of fat. The material recovered is examined for the presence or absence of enzymes and other substances and the changes which the fat has undergone. The action of enzymes, the effect of added bile, and the presence of bacteria can also be investigated. The cellular phase can be studied only indirectly in man, and at present interpretation is difficult. Investigation of the distributive phase is confined to blood-fat studies. The results in normal subjects are shown in Table III.

TABLE III.—*Detailed Study of Fat Absorption*

	Normal	Sprue Syndome
Intraluminar phase: intubation technique		
Hydrolysis	10% or more	10% or more
Emulsification	Particle diameter < 0·5 μ	Apparently normal
Bile addition . ..	Enhances lipolysis only in resting samples	Enhances lipolysis in all samples
Enzymes	Lipase, trypsin, amylase, and lysozyme present. Lecithinase absent	Lipase, trypsin, and amylase present. Lysozyme? and lecithinase absent
Bacteria . ..	Absent, or small numbers only	Present in upper intestine in large numbers
Cellular phase: Blood biochemistry Phospholipid ..	About 250 mg./100 ml.	Low. 40–200 mg. (average 142 mg. in 60 estimations)
Cholesterol	About 250 mg./100 ml.	Low < 150 mg./100 ml.
Particulate absorption ..	Present	*No* systemic hyperlipaemia
Other absorption tests ..	Normal tolerance curve	Oral glucose-tolerance curve flattened
Effect of therapy ..	Nothing conclusive	
Distributive phase: Chylomicrographs ..	Normal peak 150 particles per field	Flat
Blood-fat curves	Normal peak 200 mg./100 ml. blood	,,

2. Fat Absorption in the Sprue Syndrome

The changes observed when using these methods for the study of fat absorption in the sprue syndrome are shown in Tables II and III.

General Aspects.—In the general study of fat absorption the characteristic changes in the sprue syndrome consisted of a fat-absorption defect, only 50–70% being absorbed. The fat-loading tests show that the defect was proportionate to the amount ingested. Thus, if 50 g. were administered and 35 g. absorbed, the administration of 100 g. resulted in the absorption of 70 g. or more. With regard to fat assimilation, fats containing a large quantity of long-chain saturated fatty acids were less well tolerated by sprue patients than by normal individuals. Patients suffering from the sprue syndrome tolerated milk and milk products better than mutton fat or beef fat. The faeces contained abnormal amounts of long-chain fatty acids up to 30 g. or more in 24 hours. The neutral fat was usually about 80% hydrolysed, and the fatty acids were often present as crystals and can be shown to have a high melting point, high molecular weight, and low iodine value (Parsons, 1932; de Kamer, 1949). Volatile short-chain fatty acids were often present in large quantities.

Detailed Study.—The detailed study of fat absorption showed differences from normal. Hydrolysis and initial emulsification in the upper part of the small intestine seemed to be within normal limits. Small but significant changes in emulsification may not be detected by this method; clear differences were found in cases of obstructive jaundice or chronic pancreatitis, in which emulsification was grossly defective. The addition of bile caused enhancement of lipolysis in all samples. The reason for this difference from normal is obscure. All the usual enzymes were present in approximately normal concentration, with the possible exception of lysozyme. Bacteria were present in large numbers in the upper intestine, especially in achlorhydric patients. The bacteria found were intestinal flora, which are normally confined to the lower part of the intestine.

With regard to the cellular and distributive phases, low blood phospholipid and cholesterol were usual. The oral glucose-tolerance curve was commonly depressed. There was no post-absorptive systemic hyperlipaemia following fat absorption, as shown by chylomicrographs and blood-fat curves.

Discussion

It is difficult to study the cellular phase of fat absorption in the human subject except by indirect methods. It is agreed by all workers that long-chain triglycerides can be observed as particles in the intestinal cell during absorption, and that these particles pass from the cell through the corium of the villus to the lacteal, and thence by the lymphatic route into the blood stream, giving rise to the normal post-absorptive systemic hyperlipaemia. There is evidence to support the view that these particles pass unhydrolysed, or partly hydrolysed, into the cell from the intestinal lumen, and that adequate emulsification, normal electrolyte absorption, and possibly phospholipid synthesis may influence this stage of particulate absorption (Frazer, 1948).

Alternatively, the triglycerides are resynthesized from fatty acids and glycerol inside the intestinal cell. The post-absorptive systemic hyperlipaemia is dependent upon normal particulate absorption. Absence of the normal hyperlipaemia might be due to interference either in the intraluminar or in the cellular phase, according to the partition theory (Frazer, 1946), but according to the lipolytic hypothesis (Verzar and McDougall, 1936) it must be due to faulty resynthesis in the cell. The effect of added lipase on the post-absorptive hyperlipaemia and the normal intestinal radiographic pattern during fat absorption in human subjects support the experimental evidence in animals upon which the partition theory is based. From either point of view, however, the absence of the post-absorptive systemic hyperlipaemia must be interpreted as evidence of defective absorption of triglycerides in particulate form.

It is concluded from the evidence presented that there is interference with particulate absorption in the sprue syndrome, and that larger quantities than normal of fatty acid are both absorbed and excreted. It is not possible at present to determine with certainty whether the interference with particulate absorption occurs in the intraluminar or in the cellular phase. The more unsaturated long-chain fatty acids appear to be absorbed, while the more saturated are excreted. This would account for the proportionate nature of the defect and for a number of secondary changes which will now be considered in detail.

The Effects of the Fat-absorption Defect in the Sprue Syndrome

Intestinal Mucin.—As a result of faulty particulate absorption, greater quantities of long-chain fatty acids occur in the intestinal lumen. Administration of long-chain fatty acids resulted in an increase of mucus in the intestinal lumen in normal human subjects and experimental animals, unsaturated fatty acids being more effective than saturated fatty acids. Mucus is an activator of lipolysis in the presence of bile salts. The administration of long-chain or short-chain fatty acids or hypertonic solutions induced the so-called radiographic "deficiency pattern" in normal human subjects. The changes observed were radiographically indistinguishable from those found in the sprue syndrome. The segmentation of the barium sulphate suspension was shown to be due to flocculation in the presence of mucus. The relative proportions of mucus to barium sulphate suspension were important (Frazer, French, and Thompson, 1949). There is little doubt that more mucin is present in the small intestine in a case of sprue than in a normal individual. Whether this is due to oversecretion, or whether lack of destruction of mucin may also be concerned, has not yet been determined. An increased quantity of long-chain fatty acids is at least partly responsible for the presence of excessive quantities of mucus.

Faecal Fat.—The amount of faecal fat was increased and the output of long-chain saturated fatty acids seemed to be selective and sometimes closely associated with mucin. Long-chain saturated fatty acids are not well absorbed by normal animals. The failure to absorb these fatty acids in sprue would account for the fact that the defect is proportionate and for the observation that sprue patients do not tolerate triglycerides containing much saturated fatty acid. The more unsaturated fatty acids are presumably absorbed, and, in accordance with observations in animals, they must be transported by an alternative route to the thoracic duct and thus do not give rise to a systemic hyperlipaemia. Long-chain fatty acids may cause irritation and diarrhoea, which can be controlled by the administration of calcium salts, which precipitate the long-chain fatty acids as insoluble soap. Excessive fatty acid formation might under certain circumstances be responsible for inadequate absorption of calcium and iron. The absorption of both calcium and iron is a complex question, however, and it is unlikely that any single factor accounts for their poor assimilation in the sprue syndrome.

Hypochlorhydria.—Administration of long-chain fatty acids will cause a decrease in gastric motility and gastric secretion, particularly certain long-chain unsaturated fatty acids. In the sprue syndrome decrease of gastric motility and acidity is marked. Hypochlorhydria is usual; achlorhydria may occur. The hypochlorhydria observed in sprue may be due to the absorption of abnormal quantities of long-chain fatty acids. Hypochlorhydria and large quantities of mucin in the intestinal lumen cause a relative fixation of *p*H, which, with decreased gastric and intestinal motility and interference with absorption, help to provide suitable conditions for increased growth of bacteria. Many intestinal bacteria can split triglycerides and may help in the hydrolysis of neutral fat to fatty acid, and they may also ferment starch. Starch fermentation may be pronounced in the sprue syndrome, giving rise to volatile short-chain fatty acids (acetic, propionic, and butyric) in large quantities in the faeces. These acids may be irritant to the intestine, giving rise to diarrhoea, which is not readily stopped by the administration of calcium salts.

Blood Biochemistry.—Certain changes in blood biochemistry were usually seen, particularly a decrease of phospholipid and of cholesterol in the blood. These changes might be due either to faulty absorption or to faulty synthesis. Particulate absorption may be closely related to absorption of phospholipid and to its synthesis in the intestinal cell. Cholesterol was also found to be associated with particulate fat in the chyle. However, the quantities involved were small and no close relation between blood phospholipid, cholesterol, and triglyceride was demonstrable during fat absorption (Frazer and Stewart, 1937). It seems likely, therefore, that the changes in blood phospholipid and cholesterol in sprue may also be related to decreased synthesis of these substances in the liver or elsewhere. There is no clear evidence at present to determine whether interference with synthesis or faulty absorption is the more important factor. Large quantities of long-chain fatty acids passing direct to the liver might modify liver function.

Discussion

The probable interrelationship of these various effects of abnormal fat absorption in the sprue syndrome is indicated in Fig. 1. Faulty particulate absorption of unhydrolysed

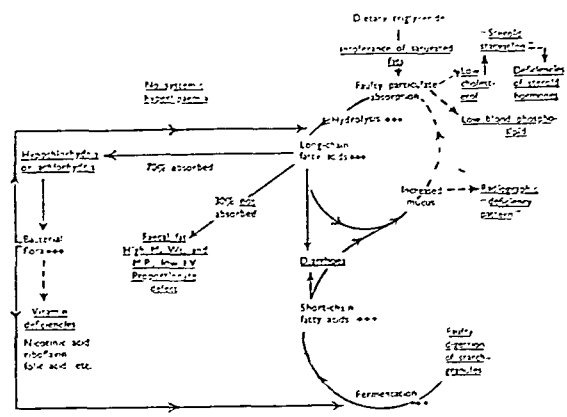

FIG. 1.—Fat-absorption defect in sprue syndrome. Continuous lines indicate points which have been demonstrated experimentally.

fat results in increased hydrolysis; the long-chain fatty acids formed are partly absorbed, causing increased mucus in the intestinal lumen; it is suggested that the excess mucus in the intestinal lumen may interfere with particulate absorption. The long-chain saturated fatty acids are not absorbed and passed out in the faeces. By taking this as the basic fault in the fat-absorption mechanism the main features of the sprue syndrome are readily explained. Thus the composition of dietary triglyceride, especially with regard to its saturated fatty acid content, will affect the sprue patient.

The absence of the systemic hyperlipaemia, although 70% of the fat is absorbed, the proportionate nature of the defect, and the occurrence of hypochlorhydria are explained on the basis of fatty acid absorption (Frazer, 1943). The failure to absorb the more saturated fatty acids is clearly shown by their appearance in the faeces. The existence of diarrhoea, which is only sometimes controlled by calcium, is due to the fact that it can be caused by long-chain fatty acids derived from fat breakdown or by short-chain fatty acids arising from starch fermentation.

The radiographic "deficiency pattern" has been shown to be due to flocculation of the barium sulphate suspension

with mucus. The changes in cholesterol and phospholipids may follow from failure of particulate absorption, or, alternatively, may be due to the effect of excessive amounts of long-chain fatty acids on liver function. Changes in steroid hormones and bile phospholipid may be secondary to the changes in blood cholesterol and phospholipid respectively. Symptoms can be aggravated in many cases of the coeliac syndrome by increasing the dietary starch (Parsons, 1932).

Relation of Fat-absorption Defect in the Sprue Syndrome to Multiple Actiological Factors

The relation of the fat-absorption defect in the sprue syndrome to possible aetiological factors is shown in Fig. 2.

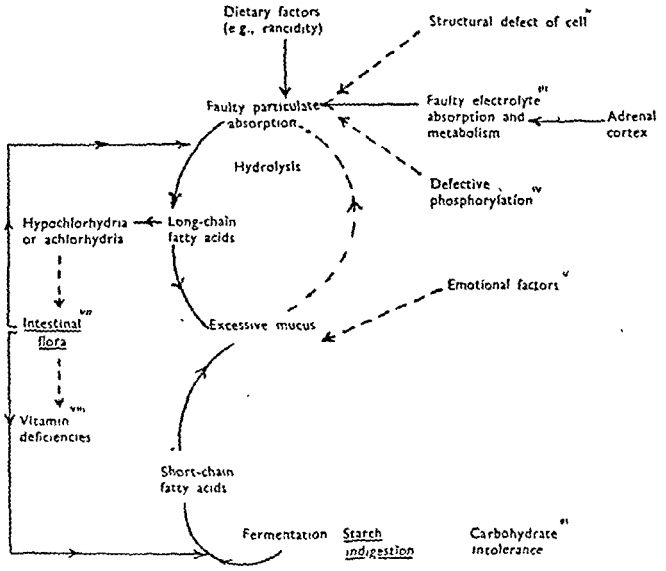

FIG. 2.—Fat-absorption defect in sprue syndrome in relation to aetiological factors.

Eight main causative factors of the sprue syndrome have been suggested, each of which will be considered briefly.

1. *Dietary Factors.*—The more saturated fats aggravate the fat-absorption defect. Special characteristics of the dietary fat, such as oxidative rancidity, may play some part in the aetiology of tropical sprue, especially when it occurs in groups of individuals under similar environmental conditions. Stannus (1942) suggested that dietary factors might have some causative role in tropical sprue. The inclusion of rancid fats in the diet causes diarrhoea, anaemia, and destruction of dietary vitamins (Whipple, 1932; Burr and Barnes, 1943; Györgi *et al.*, 1942). The possible significance of rancid dietary fats in the onset of tropical sprue in India was noted by J. M. French. It is unlikely that rancidity is a major aetiological factor in non-tropical sprue or in the coeliac syndrome in this country. Diarrhoea has been recently observed in infants in temperate climates receiving rancid cod-liver oil (Whipple, 1936). Rancid fats are readily hydrolysed, and the fatty acids liberated are irritant and are effective stimulants of mucus secretion. The effects of dietary fats and the products of rancidity on the fat-absorption mechanism are being investigated. Dietary factors may have some importance in the aetiology of tropical sprue.

2. *Structural Defect of the Intestinal Cell.*—It was suggested by Hurst (1941) that structural defects of the intestinal muscularis mucosa might be responsible for the fat-absorption defect in the sprue syndrome. Atrophic changes of the intestinal wall are not uncommon at necropsy. It is improbable that these changes are present in the many cases of tropical sprue which make a complete recovery. Secondary structural changes might perpetuate faulty particulate absorption and represent an irreversible stage of defective fat absorption in sprue cases of long standing.

3. *Disturbances of Electrolyte Metabolism (Adrenal Cortical Insufficiency).*—Adrenal cortical deficiency has been suggested as a primary aetiological factor in sprue (Verzar and Laszt, 1935), since it was thought to be necessary for phosphorylation and resynthesis of triglycerides. It has been established subsequently that the adrenal cortex does not affect phosphorylation in the intestine (Stillman, Entenman, Anderson, and Chaikoff, 1942). Low blood sodium and hypotension are not uncommon in sprue, although usually observed in severe rather than early cases (Black, 1946). Changes in electrolyte metabolism and absorption might interfere with the particulate absorption of triglycerides (Frazer, 1949). In the sprue syndrome, however, treatment with adrenal cortical hormone, corticotropin, and other measures which brought the blood sodium back to normal levels did not markedly affect the fat-absorption defect. Cases of Addison's disease may show a defect of fat absorption, but they do not develop the sprue syndrome. A low level of free cholesterol in the blood may possibly result in a generalized steroid starvation, resulting in secondary hormone deficiencies, such as adrenal cortical insufficiency and delayed sexual development. Water and electrolyte changes may contribute to the fatal termination in severe cases of sprue, but they probably are not materially concerned in the primary aetiology of the sprue syndrome.

4. *Defective Phosphorylation (Adrenal Cortical Insufficiency—Verzar).*—There is little evidence of any direct relation between phosphorylation in the intestinal cell and triglyceride absorption. Simultaneous absorption of lecithin facilitates the absorption of long-chain triglyceride (Sagrott, 1949). The amount of phospholipid formed during fat absorption may be small, and for this reason phospholipid cannot be regarded as an obligatory intermediate in fat absorption (Zilversmit, Entenman, and Chaikoff, 1948). Faulty phosphorylation of fat in the sprue syndrome has been largely assumed on the basis of flat oral glucose-tolerance curves which have been attributed to failure in the phosphorylation of carbohydrate (Verzar and McDougall, 1936; Maegraith *et al.*, 1945). Other experimental studies have not supported this interpretation of the sugar curves (Emery, 1947; Fourman, 1947). Apart from the low blood phospholipid commonly observed, there seems to be little evidence of faulty phosphorylation in the sprue syndrome. If it did occur, it might affect particulate absorption as indicated.

5. *Emotional Factors.*—These cannot be disregarded in a gastro-enterological syndrome. Movement and secretion may be affected: certain other psychosomatic disorders are associated with excessive mucous secretion. Such changes might precipitate the sprue syndrome; there is no direct evidence of the mechanism at the present time.

6. *Starch Fermentation.*—In cases of the coeliac syndrome the fat-absorption defect may be aggravated by the administration of starch. Carbohydrate intolerance in the coeliac syndrome is well known (Parsons, 1932). The primary defect seems to be faulty digestion of starch granules and consequent starch fermentation, giving rise to short-chain fatty acids. Intolerance of starch also occurs in many cases of adult sprue. An extensive investigation into the mechanism of starch granule digestion and its relation to mucinases and lysozyme is being undertaken. It is possible that starch fermentation may have an aetiological significance in some cases of the coeliac syndrome.

7. *Intestinal Flora.*—Changes in intestinal flora occur in the sprue syndrome, more affecting the site of growth than the type of organism present. The predominating bacteria may vary, however, owing to alteration in environmental conditions consequent upon faulty absorption or other changes. The higher level of intestinal flora, which may reach the upper small intestine in sprue, may give rise to successful competition of the bacteria with the host. This competition hypothesis of the common vitamin deficiencies in sprue will be more fully discussed in another communication. Changes in intestinal flora are probably secondary in tropical and non-tropical sprue and the coeliac syndrome. Intestinal bacteria can hydrolyse triglycerides and ferment starch. They could therefore initiate changes which might lead to the sprue syndrome. Such a mechanism might possibly be involved in some cases of gastro-colic fistula.

8. *Vitamin Deficiencies.*—Deficiencies of riboflavin, nicotinic acid, and folic acid are fairly common in sprue—other vitamin

deficiencies are rather rare. It has been suggested that these vitamin deficiencies constitute a primary aetiological factor in the sprue syndrome (Verzar and McDougall, 1936; Castle, Rhoads, Lawson, and Payne, 1935). There is no satisfactory evidence of a direct relation between these vitamins and the fat-absorption mechanism (Frazer, 1947b). The signs of these deficiencies can be dramatically relieved without any effect on the fat-absorption defect (Cooke *et al.*, 1946). Classical cases of deficiency of these vitamins may occur with normal fat absorption. These deficiencies, which come and go during the course of the sprue syndrome, are probably secondary changes attributable to successful competition with the host for common essential nutrients on the part of intestinal bacteria.

Conclusions

It is concluded that the underlying fat-absorption fault is a defect in particulate absorption. The consequent absorption and excretion of fatty acids account for most of the major features of the sprue syndrome. Certain intermittent characteristics may be attributed to high growth of intestinal bacteria. The primary cause of faulty particulate absorption probably varies in different cases—many cases of tropical sprue may be primarily due to dietary faults, whereas some underlying defect, possibly an enzyme deficiency, may be a major factor in most cases of non-tropical sprue and the coeliac syndrome. Intestinal flora changes occur secondarily in most cases of sprue, but they may have a more important aetiological role in some cases of gastro-colic fistula. The final picture of the aetiology of the sprue syndrome will be achieved only as a result of further detailed study of the fat-absorption defect and experimental investigations designed to differentiate primary and secondary changes.

Much of the original work referred to in this paper is still in progress as part of the programme being undertaken in the Department of Pharmacology, University of Birmingham, by a team which includes Dr. J. M. French, Dr. M. D. Thompson, Dr. H. G. Sammons, Dr. R. Schneider, Dr. P. E. Sagrott, Mr. W. R. Pover, Mr. W. D. Brown, Mr. G. A. Rowe, and Mr. B. G. Taylor. While acknowledgments are made in the text to individual members with regard to points with which they have been especially concerned, the progress of the work is essentially dependent upon the combined efforts of the whole team. I am most grateful to many colleagues on the staff of the Birmingham United Hospital, especially to Professor T. L. Hardy, Dr. W. T. Cooke, Dr. A. L. Peency, Dr. C. F. Hawkins, and Dr. Garfield Thomas, whose close collaboration and help have been invaluable. I am indebted to the Medical Research Council and the Sir Halley Stewart Trust for financial assistance in this work.

THE TREATMENT OF MALIGNANT TERTIAN MALARIA*

BY

Sir GORDON COVELL, M.D., D.T.M.&H., D.P.H.

Adviser in Malaria, Ministry of Health

The early diagnosis of malignant tertian malaria is a matter of the first importance, so that specific therapy may be started with the least possible delay. In recent years the development of modern methods of rapid transport has made it all the more imperative that medical men in all parts of the world should be familiar with the many diverse clinical manifestations of this disease.

My first experience of the difficulties which may be encountered in the diagnosis of *Plasmodium falciparum* infections occurred at an early stage of the 1914–18 war, when I was in charge of a wing of a military hospital in Nairobi. One morning about 80 British soldiers who had been evacuated from the vicinity of Lake Victoria Nyanza and sent down the line by hospital train were admitted under my care. A preliminary examination of these men disclosed a great variety of clinical symptoms, as the result of which I made a number of provisional diagnoses.

Many of the patients were obviously the victims of malaria, but there were others whose symptoms were unlike any which are usually associated with this disease. Several seemed to be suffering from some acute abdominal condition, such as appendicitis, pancreatitis, or biliary colic. Some were passing blood and mucus per rectum, and these I diagnosed as dysentery. Two or three had the clinical appearance of typhoid fever, and there were several with cerebral symptoms which I thought were probably due to heat-stroke. In one case I suspected amoebic hepatitis and in others bronchitis or broncnopneumonia. A blood smear was taken from each patient as a routine procedure and sent to the laboratory for examination; the presence of malignant tertian malaria parasites was reported in every single instance. The administration of quinine, at that time the only antimalarial drug available, was followed in all cases by prompt alleviation of symptoms and ultimate recovery.

My object in recounting this incident is to impress on those who are about to practise in malarious regions or to sail in ships which may touch at ports where the disease is endemic that malignant tertian infections often fail to conform to the popular conception of malarial fever. They may simulate a great variety of other diseases, and failure to recognize this fact has resulted in the loss of many lives which could have been saved by the prompt application of

*Read in the Section of Tropical Medicine at the Annual Meeting of the British Medical Association, Harrogate, 1949.

specific antimalaria treatment. In the past 12 months two striking examples illustrating this point have come to my notice.

Illustrative Cases

The first case was that of a young woman who visited the Victoria Falls in the course of a holiday tour in South Africa and fell ill with headache and a slight rise of temperature some 10 days later. She had no idea that she had been exposed to the risk of malarial infection, and treated herself for several days with aspirin and other non-specific drugs. Soon after reaching Johannesburg her condition suddenly became critical, and she was admitted to hospital suffering from cerebral malaria, as the result of which she died in spite of all efforts to save her life.

The other case was that of a stewardess employed in a ship on the outward run from London to Capetown. Her illness began in very much the same manner about 10 days after leaving the port of Beira, on the East African coast. Several of the crew were down with malaria, and owing to shortage of nursing staff she continued to attend to them for several days before reporting sick. When she did so, the ship's surgeon, who had had no previous experience of tropical diseases, made a provisional diagnosis of influenza and prescribed codeine. She was ultimately sent ashore at Capetown in a comatose condition and admitted to hospital. A blood smear revealed a very heavy infection with *P. falciparum*, and she was given immediate parenteral treatment with antimalarial drugs. This case fortunately ended in recovery, though during the first 24 hours after admission her condition was the cause of grave anxiety.

These two cases illustrate two characteristic features of malignant tertian malaria: (1) that the disease often has an insidious onset, and (2) that in the absence of specific treatment the patient may with little or no warning become critically ill with so-called "pernicious" symptoms, which have been variously classified as cerebral, algid, bilious, remittent, pneumonic, and cardiac. More often than not the paroxysm is ill defined and rigors are exceptional, the temperature rarely exceeding 104° F. (40° C.). A double peak in the temperature chart owing to the segmentation of two groups of parasites is common, and there may be three, four, or more groups, each segmenting independently and giving rise to continuous fever, with several peaks in the 24 hours.

It is important also to recognize that in a primary case parasites may be so scanty in the peripheral blood during the first few days of fever that they may not be detectable in a blood smear, even if no antimalarial drugs has been administered. A negative smear, particularly if this has been taken at the height of the fever, should not therefore be regarded as excluding the possibility of malarial infection. The wisest course in such cases is to administer an antimalarial drug and to take another blood smear immediately the temperature drops, when it is often possible to confirm the diagnosis.

Mode of Action of Antimalarial Drugs

It is necessary to consider this subject in relation to the various phases in the life-cycle of the malaria parasite in the human body. The recent demonstration by Shortt and his co-workers of an exo-erythrocytic phase of *Plasmodium cynomolgi* in the monkey and of *P. vivax* in man, and the subinoculation experiments of Fairley and his colleagues in Australia, have greatly clarified our knowledge of this problem, which had been for so many years a matter of speculation (Shortt and Garnham, 1948; Shortt, Garnham, Covell, and Shute, 1948; Fairley *et al.*, 1947).

Antimalarial drugs may act in four possible ways: (*a*) against the primary tissue, or pre-erythrocytic, phase of the parasite; (*b*) against the asexual parasites in their erythrocytic phase; (*c*) against the sexual parasites in their erythrocytic phase; and (*d*) against the hypothetical persistent tissue phase of the parasite, to which latency and late relapse in *vivax* malaria have been attributed (Shannon, 1948). There is convincing evidence against the existence of the last-named stage in *falciparum* infections, and only the first three categories are considered here (see Table).

Table Showing the Action of Various Drugs on P. falciparum

Class of Drug	Action on		
	Pre-erythrocytic Phase	Erythrocytic Phase (Asexual Forms)	Erythrocytic Phase (Sexual Forms)
[illegible]	−	+	−
[illegible]	−	+	−
quine, camoquin)	−	+	−
8-aminoquinolines (e.g., pamaquin, pentaquine, isopentaquine)	+	−	+
Biguanides (e.g., proguanil) ..	+	+	−*
Sulphonamides (e.g., sulphapyrazine, sulphamerazine)	−	+	−

* But prevents completion of development in the mosquito.

The cinchona alkaloids, the 9-aminoacridines, and the 4-aminoquinolines have a destructive action on the asexual parasites of all forms of human malaria in the erythrocytic phase. The sulphonamides also act on this phase in *falciparum* infections, but in view of the risk of toxic effects, particularly of agranulocytosis, this class of drugs is not generally recommended for the routine treatment of malaria. Findlay (1949), however, recorded a complete absence of toxic reactions in a group of 441 British troops in West Africa who were given a daily dose of 50 mg. of sulphapyrazine, sulphamerazine, or sulphamezathine over a period of 12 months or more, the first-named giving results superior to those with mepacrine in the prophylaxis of malaria. He suggested that the sulphonamides might be found useful for this purpose should the local strains of parasite prove refractory to other drugs, or in a case of idiosyncrasy to other drugs.

The 8-aminoquinolines do not affect the asexual parasites in the erythrocytic phase, but exert a powerful destructive action on the gametocytes. They also act on the pre-erythrocytic phase, but only when employed in dosage dangerously high for routine use. The biguanides are the only known class of drugs which can be used with safety against this phase of the parasitic cycle. They also act on the asexual forms in the erythrocytic phase. They have no demonstrable effect on the gametocytes in the peripheral blood, but render them incapable of completing their development in the mosquito.

Prophylactic Treatment

The drugs used in the prophylaxis of malaria fall into two categories: (*a*) true causal prophylactics, which act on the parasite in its pre-erythrocytic phase; and (*b*) schizonticidal drugs, which destroy the asexual forms of the parasite in the erythrocytic phase and thus suppress the overt attack.

As stated above, the only drugs at present available which exert a true causal prophylactic action against malignant tertian malaria in non-toxic dosage are the biguanides, of which the best-known example is proguanil ("paludrine"). The dosage of proguanil recommended for prophylaxis is 100 mg. daily for non-immune individuals, and 300 mg. in a single dose once weekly for indigenous inhabitants of malarious countries. A great advantage of this drug is that

it can be placed in the hands of laymen for distribution without risk of ill effect, even should the prescribed dose be grossly exceeded.

The second, or suppressant, group of drugs includes the cinchona alkaloids, the 9-aminoacridines, and the 4-aminoquinolines. For the effective suppression of *falciparum* malaria quinine has to be administered in doses of as much as 10 gr. (0.65 g.) daily, which is the maximum that can be tolerated over a prolonged period. Against New Guinea strains of *P. falciparum* even this dosage has been found insufficient, failing to prevent overt attacks during the period of its administration. Apart from the unpleasant side-effects caused by the prolonged administration of quinine, the association of this drug with the precipitation of blackwater fever renders it undesirable for use as a suppressant in *falciparum* infections.

Mepacrine, in a dosage of 100 mg. daily, is a very effective suppressant of malignant tertian malaria, provided that the drug is taken for 14 days before exposure to infection and continued for one month after leaving the endemic area. It produces radical cure by schizonticidal action, destroying the young asexual parasites after their entry into the blood stream. The dramatic fall in malaria casualties during the later stages of the 1939–45 war in the South-West Pacific and in South-East Asia was chiefly due to the general adoption of mepacrine prophylaxis by the Allied Forces, and the rigid enforcement of this measure was an important factor in bringing about the successful conclusion of both these campaigns. It should be noted that neither proguanil nor chloroquine became available for general use until after the termination of hostilities.

Despite its powerful suppressant action, mepacrine has certain disadvantages which militate against its routine use under peacetime conditions. During the first 10 to 14 days of suppressive treatment a variable degree of nausea and abdominal discomfort is not uncommon. These symptoms usually disappear completely, but persist to some extent in a small proportion of cases. Headache, insomnia, and temporary giddiness may also occur during this stage, but are less frequent. When taking the drug over prolonged periods a proportion of individuals develop skin lesions, the most common of which is a lichenoid dermatitis affecting chiefly the hands and wrists and feet and ankles. Yellow discoloration of the skin is comparatively common: this is of no great moment among troops in time of war, but is a distinct disadvantage under peacetime conditions, particularly where women are concerned.

Chloroquine is a powerful suppressant, and excellent results have been reported with a dosage of 300 mg. of the base* administered in a single dose once weekly. Its action is similar to that of mepacrine, but it is said to be considerably less toxic and does not discolour the skin. The same advantages are claimed for camoquin, with a dosage of 500 mg. weekly.

At present the choice of drug for prophylactic use would seem to lie between proguanil and either chloroquine or camoquin. The stage in the parasitic life-cycle on which the drug exerts its action is of little interest to the individual under treatment, provided that the overt attack is prevented without any injurious side-effects, and from this point of view there is little to choose between the two classes of drugs. Chloroquine and camoquin, however, do not possess the very low grade of toxicity which is so remarkable a property of proguanil, rendering the last-named drug particularly suitable for widespread administration among labour forces or other employees recruited from indigenous populations.

*= 500 mg. of the diphosphate salt.

Treatment of the Clinical Attack

Most of the literature relating to the chemotherapy of malaria published during the last few years has been based on work initiated during the war period, when the overriding objective was the maintenance of the largest possible proportion of troops in a fit condition for the conduct of military operations. We have become accustomed to relate all our activities to their effect on the war effort, and it is not always appreciated that the objects of therapy in peacetime differ in certain important respects from those obtaining in time of war. Thus, in wartime minor toxic manifestations of drugs, or even an occasional case of severe toxicity, are of no great significance, since they do not affect the fighting efficiency of the troops to any appreciable extent. But in peacetime such occurrences are of very considerable importance, both to the patient and to the physician in charge of the case.

Again, in wartime a system of treatment which will control the clinical attack and effect radical cure in the great majority of malignant tertian infections may be considered adequate. But under peacetime conditions no treatment for this disease can be considered satisfactory unless it will ensure rapid alleviation of symptoms and a high rate of radical cure, not only in the "average" case but also in abnormally susceptible individuals exposed to heavy and repeated infection in hyperendemic areas. Finally, the provision of adequate treatment for indigenous populations, which is seldom practicable whilst military operations are in progress, is usually a major feature of antimalarial campaigns undertaken in times of peace

Specific Treatment

The principal objects in the treatment of malignant tertian malaria are the termination of the clinical attack with the least possible delay, radical cure of the infection, minimum toxicity on the part of the drugs employed, and sterilization of gametocytes, so that mosquitoes which feed on patients during or after the attack cannot transmit the disease to other individuals.

Daily dosage of 20 to 30 gr. (1.3 to 2 g.) of quinine over a period of seven to ten days will usually bring about a rapid termination of the clinical attack and a high rate of radical cure. It is, however, comparatively ineffective against infections with certain European strains of *P. falciparum*. For example, James, Nicol, and Shute (1932) found that the amount of quinine necessary to control a primary attack of malignant tertian malaria caused by strains originating in the Roman Campagna and Sardinia was eight times as great as that required for infections with Indian strains of the same species of parasite. Quinine has no effect on the infectivity of gametocytes to mosquitoes, but a more serious disadvantage is that it may act as a contributory factor in the precipitation of blackwater fever. There was a striking reduction in the incidence of this disease among British troops stationed in West Africa after the substitution of mepacrine for quinine in the prophylaxis and treatment of *falciparum* infections (Findlay and Stevenson, 1944).

Mepacrine, when administered in the dosage now usually prescribed—i.e., beginning with a "loading" dose of 600 to 900 mg. on the first day or first two days of treatment, and continuing at 300 mg. daily for five to seven days—will effect a rapid termination of the clinical attack and a high radical cure rate in *falciparum* infections. The rapidity

new technique: continuous caudal analgesia. Thus, for the first time it was possible to control the pain of the major portion of active labour and that of delivery with the same technique. Happily, such a technique at the same time removed from the baby the burden of transplacental narcosis. It has been described in the following manner by Dr. J. P. Greenhill in his last edition of DeLee's *Obstetrics*: "There is no doubt that when this procedure is properly performed without any misstep there is no more satisfactory and pleasant type of analgesia in obstetrics."

It is obvious, therefore, that continuous caudal analgesia represents the combined efforts and brilliant researches of two distinguished French physicians, a Canadian obstetrician and anatomist, an English neurologist, German, Swiss, and American pharmacologists, a Mayo Clinic anaesthesiologist, a Philadelphia surgeon, and a Rumanian physician, who have placed in our hands the principles, the drugs, and the anatomical knowledge necessary to develop a single technique that is capable of relieving pain for surgery, obstetrics, and therapeutics from the xiphoid to the toes for an hour, a day, or a week.

Among the architects of this technique it would be impossible to overlook the substantial contributions of that venerable metallurgist and artisan, Oscar Schwidetzky, of the Becton Dickinson Company, who has fashioned with ingenuity the simple and compact instrumentarium.

Use in Obstetrics

The outstanding advantage of continuous caudal analgesia in this field is seen in a baby delivered without trauma, who cries and breathes and saturates his blood cells with oxygen without stimulation. This factor of baby protection is unequalled in any form of seminarcosis, narcosis, or general anaesthesia. It can be approximated only by saddle-block spinal anaesthesia and local analgesia. After a personal experience with this technique in 12,000 cases, and after training 2,000 physicians, who have reported its use in 260 scientific papers in eight languages for 600,000 deliveries, I am convinced that it offers effective and humane relief, without suggestion or hypnotism, to normal and handicapped mothers for the delivery of normal and premature babies. This opinion is shared by the 80 American obstetricians who have each managed more than a thousand deliveries under continuous caudal analgesia.

The leading United States hospitals which utilize this technique in substantial numbers are: the Beth-El Hospital in Brooklyn with 12,000 cases; the Stanford University Hospital in San Francisco with 8,000 cases; the Philadelphia Lying-in Hospital with 5,000 cases; the Syracuse University Hospital with 10,000 cases; the United States Marine Hospital in New York with 2,000 cases; the Johns Hopkins Hospital with 2,000 cases; the hospitals of Memphis, Tennessee, with 5,000 cases; the Barnes Hospital in St. Louis with 3,000 cases; and many others where nurses or doctors, trained on a 24-hour team basis, utilize this technique correctly, with the medical safeguards which protect the altered body processes in a psychological environment which maintains the patient's happiness and emotional tranquillity.

The new adjuncts of this order provided for our patients, who so often are mentally alert and who are enthralled in observing with a clear eye the actual birth of their babies, are: air-conditioning, bedside libraries, interior decorating in pastel colours, landscapes in oils and water colours, television, and well-controlled and well-selected melody and symphony of transcribed music. All or none of these pleasant interludes are provided at the direction and prescription of the attending obstetrician and of the patient herself.

Continuous caudal analgesia has returned to womankind the privilege of being present in comfort for the baby's birth. Its judicious use provides the safest labour and delivery available for patients with cardiac disease, nephritis, pulmonary disease, metabolic disease, and toxaemia. More than a score of outstanding obstetricians have declared continuous caudal analgesia to be the physician's best invitation to a premature baby for survival. In documenting this statement the Washington University Maternity Hospital from St. Louis, in a study of 591 premature deliveries (Table I), reported recently to the American

TABLE I.—*Results of 591 Premature Deliveries Among 7,650 Non-conductions, 2,500 Caudal, and 500 Saddle-block Deliveries (July 10, 1945, to December 27, 1948)*

Weight Group	Total No. in Group	Intranatal Deaths	Post-natal Deaths	Neonatal Deaths	Total Deaths	Infant Mortality
Non-conduction Group						
2,500–2,001 g.	218	5	3	9	17	7·8%
2,000–1,501 g.	75	5	1	11	17	22·7%
1,500–1,001 g.	34	6	1	11	18	52·9%
1,000–500 g.	20	10	5	5	20	100·0%
	347	26	10	36	72	20·8%
Conduction Group						
2,500–2,001 g.	138	1	0	4	5	3·6%
2,000–1,501 g.	65	0	1	3	4	6·2%
1,500–1,001 g.	28	0	0	7	7	25·0%
1,000–500 g.	13	1	0	9	10	76·9%
	244	2	1	23	26	10·7%

Incidence of premature deliveries in the non-conduction group is 4·9% (35 stillborn macerated infants included), and in the conduction group 8% (5 stillborn macerated infants included).

Medical Association that "the labours protected by conduction anaesthesia (three-quarters under caudal and one-quarter under saddle-block) show an infant mortality that was consistently at least 100% lower than that in the non-conduction group."

My experience during a three-year study, 1942–5, in the Philadelphia Lying-in Hospital coincided substantially with the Washington University report (Table II). It is my belief that if delicate premature infants, who comprise approximately 10% of obstetrical deliveries, are protected by this technique the mature babies might receive the same relative benefit.

TABLE II.—*Neonatal Mortality per 1,000 Live Births Among Full-term and Premature Infants in the Caudal and Control Groups*

	Premature Infants	Full-term Infants
Control group	227·3	6·4
Caudal group	131·7	3·0

The Philadelphia and Memphis studies show that mothers in all age groups, but particularly in the early and late extremes of the child-bearing period, benefit from this form of management (Tables III and IV).

Use in Breech Delivery.—One of my first students, Dr. Roy Nicodemus, director of obstetrics of a large Pennsylvania hospital, six years ago began the routine use of continuous caudal analgesia. In 4,000 consecutive deliveries with this technique he has managed 186 breech deliveries with an uncorrected infant mortality of stillbirths and neonatal deaths of 1.2%. He then analysed the previous 186 breech deliveries in which he had used general anaesthesia and sedation and found an uncorrected infant mortality of 6.9%. In a paper soon to be published in the American literature he concludes that this method thus lends itself favourably to the safe management of breech delivery.

TABLE IV.—*Stillbirths and Neonatal Mortality (Under 1 Week) per 1,000 Live Births Among Negro and White Mothers of Different Ages. Memphis Study, 1946*

	Age of Mother		
	Under 25	25–29	30 and Over
General	45·1	159·1	131·1
Spinal	70·8	46·5	60·0
Caudal	32·0	40·0	52·6

Use in Therapeutics

Continuous caudal analgesia through its control of nerve impulses to blood vessels and extremities and to viscera of pelvis and abdomen can be utilized as a major therapeutic measure. Its most promising field of usefulness lies in the following diseases: (1) the control and treatment of eclampsia, (2) oliguria and anuria on the basis of reflex renal ischaemia, (3) post-surgical abdominal distension and paralytic ileus, (4) arterial emboli of abdomen and lower extremities, (5) thrombophlebitis and phlebothrombosis, (6) prognosis of and indications for sympathectomy in essential hypertension, (7) the prolonged relief of post-operative or traumatic pain, and (8) sciatica and neuralgias of the lower extremities and pelvic girdle.

In 24 consecutive cases of eclampsia managed by me in the John Gaston Hospital in Memphis, Tennessee, there was a reduction in both the systolic and the diastolic blood pressures, and there was definite clinical improvement and elimination of convulsions in each case so treated. These 24 cases form part of a series of 76 that I have managed with these techniques in which there were only three maternal deaths. The infant mortality in this series was 12%. It is my contention that the substitution of continuous conduction anaesthesia for narcotic and magnesium sulphate therapy in eclampsia provides the most effective method of blood pressure and convulsion control, and permits the highest incidence of live births in this group.

A related type of vasomotor crisis is seen in the terminal coma with convulsion associated with uraemia and glomerulonephritis. An 11-year-old negro girl had a persistently mounting blood pressure, with ultimate heart failure and pulmonary oedema in spite of sedation with "aminophylline" and intravenous magnesium sulphate therapy, and even phlebotomy of 200 ml. At the point of *exodus letalis* continuous caudal analgesia in fifteen minutes, according to the indicated dosage schedule, reduced the blood pressure from 215/185 to 140/90, with the prompt restoration of consciousness, improvement of urinary outflow, and control of the pulmonary and cardiac emergencies.

Continuous caudal analgesia has presented us with an avenue of therapeutic inhibition of critical neurogenic and angiospastic mechanisms. Upon this concept lies a new horizon for the medical profession which may supersede the use of this technique in the control of pain. Its companion is the anatomically related continuous lumbar peridural analgesia as designed by us.

As continuous caudal analgesia exerts its most profound influence from below upward over the spinal nerves, so does lumbar peridural analgesia exert its influence from above downward. Either of the techniques presents the exact anatomical avenue for anaesthesia or for therapy of the organ or segment involved.

Use in Surgery

Continuous caudal analgesia is the safest and most effective technique at our disposal for operative and post-operative pain relief in haemorrhoidectomy, prostatectomy, and for operations on the perineum. By extending the levels of nerve block into the low thoracic plexus, adequate anaesthesia is produced for hernioplasty, appendicectomy, and caesarean section. We have utilized this technique in the latter three operations in more than 2,000 patients without any anaesthetic mortality. Now with continuous peridural lumbar analgesia at our disposal upper-abdominal and low-thoracic operations are more widely being managed by the extradural approach. In our hands this technique has been particularly useful for the control of pain in long orthopaedic operations which require serial *x*-ray confirmations of position and alignment of dismembered bony fragments. Even the aged and debilitated patients withstand hip-nailing operations and the like with the minimum of shock under this technique.

Drugs and Techniques.—Both techniques of the malleable needle and the indwelling catheter have been thoroughly described in the literature. The most practical recent improvement has been the substitution of the economical plastic catheter. We have extended dosage schedules and optimum concentrations of procaine, "metycaine," "pontocaine," "nupercaine," and, more recently, the safe and effective local analgesic from Sweden that is being introduced as "xylocaine."

Purely on an anatomical basis we can effectively block the afferent nerve pathways from the respective organs with the indicated dosage:

Haemorrhoids and rectum	10 ml.
Prostate and perineum	20 ml.
Bladder and uterus	30 ml.
Appendix and intestine	40 ml
Stomach, spleen, and gall-bladder	50 ml.

Continuous caudal analgesia can be intensified to a nerve block comparable with that obtained with spinal anaesthesia by a second dose, according to the scale indicated, about fifteen minutes after the first. The duration of the analgesia is entirely dependent upon the number of serial doses that are used.

Complications, Dangers, and Contraindications

Of utmost importance is a thorough knowledge of prevention of complications, amelioration of the hazards, and strict observance of the contraindications.

The most common complication is the slow or arrested labour that develops from two factors: (*a*) too early institution of the technique before progressive dilatation of the cervix to 5 cm.; and (*b*) overdosage extending the level of analgesia into mid-thoracic and upper-thoracic levels, thus interfering with the motor innervation of the uterus.

Fortunately, with the continuous method instituted through the indwelling small-gauge catheter the analgesia may be permitted to wear off and then be withheld until there is evidence of established and progressive labour. The analgesia should not be persistently maintained in the event of retarded labour unless a therapeutic advantage to either mother or baby is seen.

In my clinical experience, which is substantiated by both the Lorand and Reynolds tocodynamometer studies, approximately one-third of the labours are retarded to a

varying degree with standard dosage and segmental block; one-third are unaffected; and one-third actually suggest a clinical improvement in progress and dilatation. The second stage is definitely prolonged, since the compulsion desire to push and the abdominal somatic tone are both diminished. The usual primipara with the normal-size infant in the United States is delivered by election with episiotomy and outlet forceps. Most multiparae may be encouraged to deliver spontaneously.

The second highest complication incidence is the development of maternal hypotension, especially in the dorsal supine position. In large measure this is mechanical, through the production of a bloodless phlebotomy into the dilated vessels of the lower extremity. In some 5,000 carefully analysed cases this complication presented itself in 22% of the cases. The usual range of systolic reduction was from 120 to 90 mm. Hg.

The incidence may be greatly decreased by the prophylactic use of the vasopressor drug in all individuals with normal or low blood pressure, and in the maintenance of proper hydration, especially during hot weather. Hypotension may be combated by: (*a*) intravenous vasopressor drugs in minute 10-mg. doses of ephedrine or the equivalent *pro re nata*, (*b*) intravenous fluids containing glucose, (*c*) high atmospheres of inhaled oxygen, and (*d*) autotransfusions by raising the lower extremities to right-angles with the long body axis to produce a gravity return of the venous blood. In cases with severe varicose veins elastic stockings should be applied.

In our experience the mother tolerated extremes of hypotension, even a systolic pressure of 60 mm. Hg, better than the baby, who on occasion developed a bradycardia when a maternal systolic pressure below 80 mm. Hg was neglected for five minutes or longer. Even under these circumstances we have delivered babies with normal arterial and venous cord blood oxygen, provided the mother at the time was inhaling rich oxygen atmospheres. A few cases of loss of foetal life *in utero* or shortly thereafter have emphasized to several observers the importance of maintaining maternal blood pressure.

A third complication formerly greatly feared is the inadvertent spinal or subarachnoid anaesthesia of overwhelming proportions with the usual caudal dosages. The institution of the test dose and the ten-minute wait before proceeding and the institution of a low, safe, continuous spinal or saddle-block analgesia for these cases through intentional election have served to minimize this hazard. Inadvertent puncture of the spinal canal, with the usual insertion of a needle 6 cm. into the canal, has occurred under supervision only about once for each 500 cases. In some we elect to abandon the procedure, but in others we prefer to institute continuous spinal analgesia with usually one-thirtieth to one-fifteenth of the recommended dose. Careful aspiration of the indwelling caudal needle before insertion of the catheter reveals spinal fluid in almost all the small fraction of cases with low-lying durae.

Another complication that was formerly greatly feared is infection about the site of injection. With careful cleanliness and antisepsis and gloved technique, the incidence of infection is now about 1 in 1,000 caudal deliveries. The majority of these are simple pin-point pustules from the needle puncture. About one case of cellulitis or peridural infection occurs in each 5,000 deliveries under continuous caudal analgesia. With the prompt institution of the antibiotic drugs this type of infection can often be controlled. Nevertheless, with proper technique and proper care of equipment it can be prevented. In the control of eclampsia we have maintained continuous caudal analgesia for periods of one week without producing any demonstrable nerve irritation.

The fifth type of complication is that due to individual toxicity to the various local analgesics. It is characterized by immediate and persistent nausea and vomiting accentuated by each dose of the local analgesic, by tachycardia, by dizziness, and by hyperirritability. In nearly every instance we have achieved satisfactory results by the substitution of another local analgesic, such as procaine or pontocaine for metycaine, or vice versa.

The contraindications are as follows: (1) inadequate training or skill on the part of the operator; (2) substandard home or hospital conditions which do not provide the safeguards of available oxygen, vasopressor drugs, intravenous fluids, and proper asepsis; (3) local infection or skin irritation at the site of needle puncture; (4) gross abnormalities obliterating sacral hiatus or deformities of the vertebral column, which preclude the proper distribution of the anaesthetic agent; (5) central nervous system disease or disease of the vertebral column, such as tuberculosis, syphilis, etc.; and (6) previous laminectomy.

Summary

In America continuous caudal analgesia has been used for more than 600,000 deliveries. It has proved its capacity for relieving pain in surgery, obstetrics, and therapeutics from the xiphoid to the toes for an hour, a day, or a week. Its proper application eliminates transplacental narcosis and pharmacological retardation of vital baby reflexes.

Through such a mechanism of labour the premature baby is spared drug depression and the traumas attendant upon delivery through an unrelaxed birth canal.

More than 200 medical papers in eight languages have concluded that infant mortality and morbidity have been reduced with continuous caudal analgesia.

Under its management the third stage of labour is shortened and post-partum blood loss approaches the minimum. Post-partum complications are conspicuous by their absence.

Mothers with toxaemia, heart disease, and respiratory and metabolic infirmities are spared most of the stress and strain of labour.

It has been used in the control and treatment of eclampsia in more than 100 cases, with a maternal mortality below 5% and an infant mortality below 15%. Dieckmann, of Chicago, has described it as the outstanding advance in the treatment of this disease of our present decade. Greenhill, of Chicago, has declared: "There is no more satisfactory and pleasant type of analgesia in obstetrics."

The indwelling-catheter method of administration makes it simple and easy to apply for prolonged periods.

In proper dilutions all of the standard local analgesic agents in volume sufficient to block the 16 afferent nerve pain pathways from the uterus provide complete maternal comfort in 85 to 92% of cases.

The complications have been sharply delineated and methods of their prevention and treatment are presented.

The incidence of forceps deliveries is increased. In those clinics where this is considered to be undesirable this technique will still prove to be invaluable in permitting slow deliberate forceps delivery of the parturient woman arrested in the second stage of labour.

The technique has been used successfully for all types of rectal, perineal, and lower abdominal operations and for orthopaedic procedures on the lower extremities.

In the treatment of thrombophlebitis it provides easy access to the sympathetic nerves, which Leriche blocked through the paravertebral approaches. In America continuous caudal analgesia with a single-needle catheter technique is replacing the four needle insertions of lumbar paravertebral block.

Other therapeutic applications in treating arterial emboli, reflex anuria, abdominal distension, and vascular insufficiency have been described.

Continuous caudal analgesia has been determined of great value in the prognosis of sympathectomy for essential hypertension.

It opens a new avenue for the prolonged control of post-operative and intractable pain in terminal carcinomatosis.

Finally, the medical profession and I personally express our gratitude to our European colleagues who in 1901, after careful researches, made possible this medical technique which it has been my privilege to extend into these various applications.

SOME OBSERVATIONS ON PULMONARY TUBERCULOSIS IN THE NIGERIAN AFRICAN

BY

B. S. JONES, M.D., F.R.C.S.Ed.
Specialist, Colonial Medical Service, Lagos, Nigeria

Pulmonary tuberculosis is moderately common amongst the Nigerians, but, though cases now report more often to the hospitals for treatment, there is no conclusive evidence that its incidence is rising significantly. Anticipated measures for the control of the disease in Nigeria are likely to meet with little success unless close account is taken of its particular characteristics in the African, and it is hoped that the following observations may serve to stress some of its features. The series of cases, though consecutive, is admittedly very small, but supports the conclusions drawn from a large number of additional cases seen during the last eleven years, but in which observations and investigations were less complete.

The peculiarly virulent nature of pulmonary tuberculosis in the African is still sometimes attributed to a relatively recent introduction of the infection by the European to a country and people not hitherto exposed to it—a so-called virgin soil. It is probable, however, that the disease was introduced long before the advent of Europeans in significant numbers, possibly from the North and Near East by the old trans-Sahara trade routes. Conceptions of the importance of a virgin soil seem to imply that an inherited immunity can be established as a result of several generations of exposure to infection, but the example of the American negro furnishes no evidence in support of this supposition or in favour of a possible progressive genetic elimination of the highly susceptible. Though improvement in education, economic status, and standard of living may do much to mitigate the severity of the disease amongst the population as a whole, it seems that the violence of the disease in the African must be explained on a basis of his inborn constitutional peculiarities.

The common impression in Nigeria is that pulmonary tuberculosis in the African is not amenable to treatment and is invariably fatal. That the outlook is not so hopeless as this Davies (1946) has shown as a result of twenty years' work in Tanganyika. He points out that by the time a patient presents himself voluntarily for treatment his disease, so rapid is its advance in the African, is already hopeless of cure, and such indeed is the experience in Nigeria. Apart from the obvious necessity for education of the public and for improved living conditions, isolation of the open case is a prime essential. Davies stresses that for this purpose, and for the detection of cases early enough for effective treatment, sanatoria working as isolated units are no more effective than the existing general hospitals, for both are dependent on the voluntary attendance of patients. Only by the institution of travelling teams equipped for clinical examination, mass skin tests, and miniature radiography, designed to detect the early case and the susceptible individual, and of spaced bush dispensaries based on regional sanatoria, can satisfactory results be anticipated.

Incidence of Tuberculous Infection

Skin Tests.—Table I shows the results of Mantoux tests with 1 in 5,000 old tuberculin on 93 hospital in-patients, chiefly Northern Nigerians, not exhibiting any demonstrable tuberculous lesion. Table II gives the Mantoux results with 1 in 500 old tuberculin in 43 similar in-patients, while Table III shows the findings with 1 in 500 old tuberculin in 93 male scholars of a Government secondary school, all Southern Nigerians aged between 13 and 16 years. It is evident from these results that 65% of the more urban sections of the community in their mid-teens and 80% of those in the 20–29 age group and onwards have experienced a tuberculous infection.

TABLE I

Age Group	0–9	10–19	20–29	30–39	40–49	50 and Over
Positive	0	6	13	7	13	8
Negative	3	13	9	7	9	5
Proportion positive	0%	32%	59%	50%	59%	61%

TABLE II

Age Group	0–4	5–9	10–14	15–19	20–29	30–39	40–49	50 and over
Positive	1	2	2	3	8	3	4	4
Negative	4	5	1	1	2	1	1	1
Proportion positive	20%	29%	67%	75%	80%	75%	80%	80%

TABLE III

Negative	Weakly Positive	Strongly Positive	Total Positive
32	10	51	61 (65·6%)

Necropsy Evidence.—In a series of 90 consecutive routine necropsies carried out on the cadavers of patients who had died in one hospital of conditions other than tuberculous a search was made for latent or healed tuberculous foci. Almost all of the lesions so encountered were sent to the Lagos laboratory for microscopical confirmation. The results are given in Table IV.

TABLE IV

Age Group:	0–9	10–19	20–29	30–39	40–49	50 and over	Total
Pulmonary focus	0	0	0	1	1	1	19 (21·1%)
Hilar or broncho-mediastinal gland focus	0	0	3	1	2	1	
Pulmonary + hilar gland foci	0	0	0	1	1	1	
Abdominal gland focus	0	0	2	1	1	0	
Pulmonary, hilar gland, and abdominal gland foci	0	0	1	1	0	0	
No tuberculous focus	6	6	18	13	20	8	71 (78·9%)
Proportion with tuberculous foci	0%	0%	25%	28%	20%	27%	

It is observed that of these 90 cadavers 19 (21.1%) showed easily demonstrable healed or latent tuberculous foci. The employment of specialized methods would

undoubtedly have revealed a far higher percentage. The pulmonary lesions were usually subpleural and most commonly took the form of small gritty areas of fibrosis and anthracosis containing caseous foci from the size of a pinhead to ¼ in. (0.3 cm.) diameter. Larger encapsulated caseous foci were much less common. In the case of the hilar gland lesions the glands were usually a little enlarged, anthracotic, and contained similar pinhead, grey or yellow caseous foci. The abdominal glandular lesions are of some interest, as milk rarely enters into the dietary of these people, and in one or two cases the site of the lesions was not altogether suggestive of an intestinal portal of entry. Thus one cadaver with tiny caseous foci in the left upper lobe and associated broncho-mediastinal glands exhibited also gross enlargement and old caseation in glands at the root of the mesentery. A second showed tiny caseous foci in two of the right para-aortic abdominal glands as the only demonstrable tuberculous focus. Old pleural adhesions were encountered in 75% of the cadavers.

Clinical and Necropsy Observations in Cases of Pulmonary Tuberculosis

The clinical and post-mortem findings in 36 consecutive cases of tuberculosis with pulmonary lesions treated in one hospital have been analysed and summarized. Patients admitted during this period who absconded or on whom necropsy was refused have been excluded. The patients were Northern and Southern Nigerians, with a considerable preponderance of the former. Although the disease pursued an essentially similar course in the two races, it was the impression that the Northerners showed a rather lower resistance than the Southerners. Complicating factors are always common in these people, malaria being universal, intestinal helminths almost invariable, and filariasis, bilharziasis, dracontiasis, chronic amoebiasis, and malnutrition occasional. By clinical and necropsy criteria five types of case could be distinguished, the respective features of which are detailed below.

Type 1

This group comprised 23 cases, the extremes of age being 18 and 64, and the average age 36. Seven patients were over 45. All complained of productive cough, weakness, and weight loss, several of diarrhoea, six of hoarseness due to associated laryngitis, six of chest pain, and only three of haemoptysis. In all there were obvious physical signs in the chest, usually bilateral, and in all the sputum was profuse and acid-fast bacilli were easily found, often in large numbers. All cases showed a moderate to severe hypochromic anaemia, and in over half the cases there was a leucocytosis of 12,000 to 16,000, usually with a polymorphonuclear percentage of between 75 and 90, and no monocytosis. It should be mentioned that in 44 average healthy Africans the mean white cell count was found to be 6,807 (polymorphonuclear neutrophils 59%, lymphocytes 31%, monocytes 4.6%, eosinophils 4.4%).

In all cases in which it was determined the B.S.R. was between 50 and 70 mm. in one hour, except for one of 20 mm. and one of 2 mm. All showed some pyrexia, remittent or intermittent, with evening rises to 100–102° F. (37.8–38.9° C.). Weight loss varied between ½ and 3 lb. (0.22 and 1.36 kg.) per week, and the average interval between the alleged onset of symptoms and death was seven months, the extremes being two and 13 months. Admittedly this estimate of the average duration of life excludes a few of the less severe cases, in which the patients, either because of lack of progress in hospital or because treatment had resulted in sufficient amelioration to induce in them undue optimism, absconded and were excluded from the series.

I have, apart from the present series, kept more favourable cases under observation and treatment for as long as two years before they defaulted in their attendance. Yet I have never, under existing conditions, encountered a case that had been permanently cured or offered promise of being so. As regards treatment, I have during the last ten years employed collapse therapy, artificial pneumothorax, often bilateral and partial, alone or in combination with phrenic evulsion, in a considerable number of cases. The majority of the patients showed bilateral involvement, were too advanced to be truly suitable, and derived no significant benefit. However, the few less hopeless cases showed enough improvement to suggest the probable effectiveness of collapse therapy if cases could be detected and brought under treatment at an earlier stage. Suitable antibiotics have not been available.

At necropsy there was very extensive cavitation of one or both upper lobes. Often the whole of one upper lobe would be represented by a huge cavity bounded only by the greatly thickened and densely adherent pleura. Evidence of fibrosis limiting the cavities before the pleura was reached was very rare and never marked, except in one case which showed sufficient gross fibrosis to produce tracheal displacement. Exceptionally, cavitation was more extensive in a lower lobe. The condition of the remaining lobes was variable, but rarely were they normal and healthy. Very often there were more or less large areas of whitish caseous pneumonic infiltration, sometimes, when extensive, with central cavitation. Often there were isolated clean-cut spheroidal cavities about 1 in. (2.5 cm.) in diameter and containing fluid pus.

In most cases there were the scattered diffuse single and trefoil lesions of tuberculous bronchopneumonia. Occasionally a lobe might have an appearance of hepatization. The hilar glands were fibrotic and anthracotic, but rarely showed macroscopic tuberculous lesions. There were in the majority typical tuberculous ulcers of the ileum, with white thread-like infiltration of the associated lymphatics and caseous foci in the regional mesenteric glands. Apart from this latter, gross lympho-glandular lesions were absent, as also were miliary lesions. In only three instances were primary tuberculous foci detected. One showed a typical Ghon lesion at the left apex, and in the right upper lobe several old inspissated caseous foci, some partly calcified, varying in size from a pinhead to a peanut and surrounded by considerable fibrosis. Another showed old pinhead foci of caseation with surrounding fibrosis and anthracosis in an upper lobe, and the third two mesenteric glands converted to mere fibrous shells enclosing old inspissated caseous matter.

Type 2

Eight cases fell into this group; the ages ranged from 17 to 42, the average being 29. The invariable complaints were of productive cough, weakness, and weight loss. Obvious clinical chest signs were present in all, and acid-fast bacilli were always found in the sputum, usually in profusion. The blood count as a rule was characterized by a moderately severe hypochromic anaemia, and in five cases a leucocytosis of from 11,700 to 25,600 with polymorphonuclear percentages from 74 to 91 and no monocytosis. The B.S.R. lay between 60 and 70 mm. in one hour in all cases except one, in which it was only 3 mm. Pyrexia was remittent or intermittent, with rises to 101–103° F. (38.3–39.4° C.); the average weekly weight loss was 2½ lb. (1.13 kg.); and the average interval between the professed onset of symptoms and death 4½ months, the extremes being 1½ and eight months.

The common necropsy finding was very extensive areas of whitish tuberculous caseous pneumonia with small or moderate-sized central cavities where the caseous matter had broken down. The intervening lung might have an appearance of grey or gelatinous hepatization, while often the tiny diffuse lesions of tuberculous bronchopneumonia were found elsewhere. Tuberculous ileal ulcers with caseation of the associated mesenteric glands were usually present. There was always gross enlargement and caseation of broncho-mediastinal and/or cervical and abdominal lymphatic glands. Seven of the cases showed miliary lesions in one or more of the liver, spleen, and kidneys, and while the hepatic and renal lesions were typical milia the splenic foci were often larger, up to about ½ in. (0.6 cm.) in diameter. Three cases showed primary tuberculous foci—one a caseous pulmonary area ½ in. (1.25 cm.) in diameter with surrounding fibrosis and anthracosis, and the other two

small yellow caseous pulmonary foci from the size of a pinhead to ¼ in. diameter with surrounding fibrosis.

Type 3

There was only one case of this type, that of a man aged 34 who had complained of retrosternal pain and unproductive cough for two weeks. He was found to have a pericardial effusion and congestive cardiac failure, and died within a few days. At necropsy a grossly thickened parietal pericardium was found and an equally thickened and shaggy visceral pericardium, reported microscopically as tuberculous. The right lower lobe pleura was adherent and the upper lobe pleura opaque and markedly thickened. In the hilar zone of the right upper lobe were cavities the size of a peanut filled with old caseous matter; more peripherally were a few pinhead caseous foci and dense fibrosis of the whole area. This was reported by the pathologist as "a very chronic tuberculosis with great fibrosis and hyaline degeneration." In the right lower lobe and both left lobes were a few scattered pinhead caseous foci; in the left upper lobe there was an encapsulated caseous focus the size of a peanut. The hilar and broncho-mediastinal glands were a little enlarged and anthracotic, and contained small caseous foci. The mesenteric glands were enlarged and yellowish, and showed caseous areas.

Type 4

There were three patients in this group, aged 17, 19, and 27. The complaint in all cases was of weakness, weight loss, and cervical swellings. Clinically there were diffuse cervical and in one case also axillary lympho-glandular enlargements, retrosternal dullness, and intermittent pyrexia with evening rises to 100–102° F. (37.8–38.9° C.). There were a moderate or severe hypochromic anaemia, a slight leucocytosis of 10,000 to 12,000 with a relative polymorphonuclear preponderance, and a B.S.R. between 60 and 70 mm. in one hour. One case had thin purulent left pleural and peritoneal effusions, and necropsy showed many tiny subpleural tubercles. The salient post-mortem findings were diffuse enlargement with gross caseation, but no liquefaction, of broncho-mediastinal, cervical, abdominal, and possibly also axillary lymphatic glands, gross miliary tuberculosis of the lungs, and miliary tubercles in the spleen, and in one case also in the liver. Two cases showed coincident portal cirrhosis with splenic and hepatic enlargement.

Type 5

The one case of this type, that of a man aged 50, may represent a modification of type 4, but certain differences were apparent. The case had proved puzzling owing to an associated maculo-anaesthetic leprosy. At necropsy both lungs were riddled with tuberculous bronchopneumonia. Near the left apex was a caseous lesion 1 by ½ in. (2.5 by 1.25 cm.), subpleural, without macroscopic limiting fibrosis but with an old overlying pleural adhesion. This was reported by the pathologist as "not a chronic lesion, but presumably the primary lesion of the recent infection, the pre-existing pleural adhesion being the determining factor of its site." Within one or two inches of this lesion were several zones of anthracosis and two small pinhead caseous foci reported as showing central scarring. The hilar glands were a little enlarged and contained caseous foci, and one, on section, was reported as "an old caseous encapsulated focus with some more recent tubercles." The more proximal broncho-mediastinal glands and the para-aortic glands in the abdomen were enlarged in lumpy masses, caseous and with liquefaction; splenic, pyloric, hepatic, and cystic glands were all moderately enlarged and grossly caseous. Cervical and axillary glands were greatly enlarged and confluent, and showed caseation and liquefaction. There was one tuberculous ileal ulcer, and the spleen and kidneys contained miliary tubercles.

Discussion and Conclusions

It is apparent that infection with the tubercle bacillus is now widespread, at any rate in the more populous areas of Nigeria, the primary infection being incurred usually in childhood or adolescence.

Progressive pulmonary lesions are rarely encountered in subjects under 17 years of age. It is recognized that such lesions can develop only if and when the lungs have acquired a high degree of sensitization to the products of the tubercle bacillus. It is thus evident that such allergy is not as a rule fully developed till after the age of approximately 17 years. The allergy responsible for the exhibition of a positive skin test, which is acquired as early as three months after the primary infection, must thus represent but one aspect of the process of sensitization. It seems that the attainment of sensitization to certain other fractions of the tubercle bacillus must extend over a period of years, its rate and degree varying possibly with the age incidence or dose of the primary infection or, more probably, with the number and frequency of early reinfections.

Further, the prevalence of tuberculosis of particular systems at particular age periods suggests that the various systems and tissues may attain maximum allergy at differing intervals from the primary infection. As an instance tuberculous adenitis in the European is most commonly seen in childhood, and is usually explained as a separate entity by postulating a distinct tonsillar or pharyngeal portal of entry, the result of a tendency on the part of young children to carry everything to their mouths. In the Nigerian I have most frequently encountered the disease among adolescents and young adults, while milk and milk products form no part of the dietary of the Southern Nigerian.

Though the communal eating-pot may provide a possible means of infection by ingestion, it seems equally possible that tubercle bacilli, entering by the usual method of inhalation of dust or droplets, may reach the cervical glands by lymphatic channels from the previously infected broncho-mediastinal glands. They there remain latent till later attainment of full allergy by the lympho-glandular system, possibly with the added precipitating factor of an intercurrent non-tuberculous infection of teeth, tonsils, or pharynx causes the appearance of manifest cervical glandular lesions. It is thus suggested that glandular tuberculosis should be regarded, like pulmonary tuberculosis, as a possible milestone on the path of any tuberculous infection, and not necessarily as a separately determined entity, and that every subject of a primary infection subsequently, over a period of years, passes through a stage of lympho-glandular sensitization, a later stage of pulmonary sensitization, and a final stage of desensitization.

Despite the extreme virulence of pulmonary tuberculosis in the African, the vast majority, although exposed to tuberculous infection, do not develop cavitative lesions. Further, the disease is not exceptionally prevalent among the African nursing staffs of medical wards—an observation consistent with the relative infrequency of the disease among European sanatorium staffs and the marital partners of open cases. The possible inference that the majority of such adults have attained to a state of desensitization does not seem probable, for they fall within the age period at which clinical phthisis is most frequent and therefore pulmonary allergy presumably maximal. It seems more likely that they have been predestined by early reinfections, either very infrequent or of small dosage, to a low subthreshold peak allergy, the course of which later adult reinfections are powerless to influence.

The typical phthisis of the European, with its features of fibrosis and chronicity, is not encountered in the African. The counterpart in the Nigerian—the type 1 group described above—is a rapidly fatal cavitative disease in which rapid weight loss, high pyrexia, concurrent caseous pneumonic lesions, absence of fibrosis, and often a leucocytosis with

myoidema was recorded at the same examination, except for the troopship population, in whom myoidema only was looked for.

Analysis of the incidence of vitamin deficiency signs showed: (1) Indian troops on duty in Syria-Lebanon had a lower incidence of deficiency signs than those in hospital; this was not so in Iraq. (2) The meat-eating patients in hospital (Syria-Lebanon) showed a lower incidence of deficiency signs than vegetarian patients. (3) The British troops had a lower incidence of deficiency signs than the Indian troops. (4) Indian troops and hospital patients in Syria-Lebanon had a lower incidence of deficiency signs than those in Iraq: the hospital patients in Syria-Lebanon showed a lower incidence than men on duty in Iraq. These findings suggested that severe myoidema and vitamin deficiency were possibly related.

Myoidema and Chest Pain

The commonest complaints of medical out-patients in our general hospital in Iraq in 1944 were pain on each side of the chest and loss of appetite, general weakness, and general aches and pains. Men with these complaints often had painful severe myoidema and active tendon-jerks. Some patients complained of giddiness, and others of cramps in the calf muscles and sciatic pain. Scores of such men were seen at the end of the hot weather, and were sent to hospital with such diagnoses as myalgia of the chest, neuralgia, fibrositis, pleurodynia, pleurisy, and sciatica. Many were sent for investigation of supposed early tuberculosis or cardiac disease and were unnecessarily submitted to *x*-ray and other examinations. Some were given procaine injections for supposed fibrositis.

Chest pain was the commonest single symptom, and was complained of as a constant diffuse ache on both sides of the chest. This pain usually disappeared after thiamin injections had been given for 10 to 20 days, or after longer periods if yeast tablets were taken. The frequency with which pain in the chest responded to thiamin was striking, but under field conditions a controlled experiment was not possible. It was thought that this pain was associated with fatigue of the chest muscles, which were presumably in an early pathological condition, as shown by severe myoidema. Patients recovered when thiamin was given. Many of these patients were seen by a psychiatrist, because the symptoms were often excessive fatigue, exhaustion, and depression, but in most cases no psychiatric abnormality was found. The same symptoms, however, were often absent in men on duty who were found to have severe myoidema. We had the impression that the incidence of severe myoidema was greater at the end of the hot weather. Routine urine examinations showed no salt depletion.

Cause of Myoidema

Kollert and John (1925) reported that 40% intravenous glucose abolished or diminished myoidema; they suggested that the sign was related to failing carbohydrate metabolism. The addition of insulin increased the effect of intravenous glucose. John and Dattner (1926) considered that in a number of conditions producing vasomotor disturbance myoidema was always present, and the capillaries in these patients showed thickening, tortuosity, and absence of contractility. They thought that intravenous glucose improved the contraction of capillary walls, increased the blood flow, and brought about disappearance of myoidema. Grill (1927) found that a large number of patients showing myoidema had raised lactic acid levels in the blood.

Koumans (1928) reported myoidema to be a common finding in poor-class Javanese, Malays, and Chinese in the Tropics. Their well-to-do counterparts and the Europeans, even after a long stay in the Tropics, did not show myoidema. He found it had *no relationship* to any disease, to overexertion, to the blood-sugar level, or to deficient carbohydrate intake, but was related to unbalanced diet and undernutrition. He regarded myoidema as a sign of avitaminosis. John (1928), criticizing Koumans's paper, stated that myoidema did occur in cases showing no avitaminosis. Seto (1937), working in Japan, confirmed Koumans's findings.

Denny-Brown and Pennybacker (1938) made electromyographic studies of two cases showing myoidema and, citing the work of Gelfan and Bishop (1932, 1933) and Gelfan (1933–4), were of the opinion that the phenomenon was due to a disturbance of the excitability of muscle fibre, predominantly of its contractile contents. They postulated a disturbance of the potassium : sodium ratio and the raising of excitability of both sarcolemma and muscle fibre. These workers were of the opinion that in a normal muscle percussion induced a "small knot of contraction with tightening of the remainder of the fasciculus," and that both subsided in one to five seconds, according to the intensity of the stimulus. If the local contraction lasted more than 10 seconds they regarded it as abnormal. Smart and his collaborators (1948), studying Belgian workers who were receiving inadequate food, found the biceps "ridge" lasted longer in them than in healthy R.A.F. personnel (about 4.5 seconds and 2.1 seconds respectively), but the phenomenon decreased in duration after food supplements had been given. They could not indicate which biochemical lesion produced the hyperirritability.

Analysis of the association of severe myoidema with coincident illness, dietetic habit, and vitamin deficiency suggested that in our cases the sign denoted malnutrition. The evidence for associating myoidema with disordered thiamin metabolism was that in 51 cases of neuritis treated with thiamin myoidema decreased and in many cases disappeared. Thiamin also cured the associated chest pain and muscular tenderness. The part played by thiamin, however, may have been an indirect one, by restoring the appetite.

Under certain conditions severe myoidema may be a pre-neuritic phenomenon. Peripheral neuritis was common in our garrison, and all the cases had severe myoidema. The incidence of severe myoidema among troops on duty was also high: they often had tender muscles, pain in the chest and calf muscles, cramps, and exaggerated tendon-jerks, like those seen in early cases of neuritis in our series.

Since the men's rations were stated to contain normal quantities of thiamin (3 mg. daily) other causes for disordered thiamin metabolism were considered. Thiamin deficiency may have been due to loss of appetite, to diarrhoea, and to loss in sweat (especially during the hot weather, when sweat loss amounted to over 10 pints (5.7 litres) daily). An attack of fever, or extra marching, may have precipitated thiamin deficiency by increasing thiamin requirements.

Summary

Severe myoidema was found in South Iraq in a series of cases of peripheral neuritis in soldiers on duty and in patients suffering from other diseases.

The condition was related to the nutritional state and the dietetic habit of the groups of men examined. It accompanied signs of vitamin deficiency, and disappeared when the cases of peripheral neuritis were treated with thiamin. It is suggested

that in our cases severe myoidema was a sign of malnutrition and was probably related to thiamin metabolism.

An explanation is attempted of the growing disrepute of myoidema as a physical sign.

We wish to thank Mr. C. K. Dilwali, statistical officer, directorate of inter-Service statistics, Supreme Commander's Headquarters, New Delhi, and his assistant, Mr. K. C. Gupta, for their help in the analysis of our statistics. We are grateful to the D.M.S., India, for permission to publish this paper.

LYMPHADENOPATHY IN BRUCELLOSIS

BY

HUGH CONWAY, B.Sc., M.B., M.R.C.P.

Assistant Physician to Out-patients, Western Infirmary, Glasgow; late Medical Specialist, R.A.M.C.

Lymphadenopathy is not a prominent feature of brucellosis. Most of the textbook articles on the subject make no mention of the lymph nodes. Bloomfield (1942) made an extensive survey of published case reports in an attempt to discover if specific lymphadenopathy ever occurs in Brucella infections. He found that most authors omitted all reference to the nodes, and detailed information was difficult to obtain. He concluded, however, that noteworthy enlargement of the superficial glands was not uncommon, although its significance was seldom clear because the available data on the clinical course of the adenitis in relation to the progress and outcome of the disease were usually inadequate.

In view of the confusion, it was decided to make a careful clinical examination of the lymph nodes in patients suffering from melitensis fever in a military hospital in Malta. The series consisted of 42 cases, all the patients being under observation in hospital throughout the course of their illness. In 30 the diagnosis was proved by blood culture; in 11 repeated blood cultures were negative, but melitensis agglutinins were present in the sera in titres varying from 1 in 1,280 to 1 in 20,480; in the remaining case blood cultures and agglutination tests were negative and the diagnosis was made on purely clinical grounds. Generalized superficial lymphadenopathy was an outstanding initial feature in two patients, and in both instances caused difficulty in diagnosis. The other 40 cases were entirely free from lymph-node involvement during their stay in hospital.

Case 1

A Maltese man aged 21 was admitted to hospital on December 3, 1945, with a provisional diagnosis of glandular fever. His complaint was of headache, anorexia, and shivering attacks for five days. He looked very ill and his temperature was 102.4° F. (39.1° C.). There was bilateral and symmetrical enlargement of the cervical (anterior and posterior), axillary, epitrochlear, and inguinal lymphatic glands. The glands were mobile, discrete, firm, and non-tender, and varied in size from 1 to 2 cm. in diameter. The throat was clean. There was no enlargement of the liver or spleen. The leucocyte count was 6,850 per c.mm. (polymorphs 20%, lymphocytes 51%, monocytes 29%—a fair proportion of the latter resembled "glandular-fever cells"). The Paul-Bunnell test was positive in a titre of 1 in 32.

In the first few days the temperature intermitted between 104° F. (40° C.) and normal; the patient had several rigors and severe epistaxis occurred on three occasions. He complained bitterly of neuralgic pains in his arms and legs. The cerebrospinal fluid was normal. An initial diagnosis of glandular fever was made, but six days after admission his serum agglutinated *Br. melitensis* in a titre of 1 in 10,240. Blood culture was performed on the same day, and after 14 days' incubation a profuse growth of *Br. melitensis* was obtained. A radiograph of the chest showed no enlargement of the mediastinal glands. The acute symptoms subsided slowly and the temperature fell by lysis after remaining high for 10 days.

The subsequent course was typical of that pursued by a severe case of undulant fever—recurring bouts of fever, progressive anaemia, and flitting arthritis. The glands decreased in size very slowly, and by the end of the sixth week none were palpable. The Paul-Bunnell test was repeated twice and remained positive in the same titre (1 in 32). In the sixth week the leucocyte count was 6,700 per c.mm. (polymorphs 45%, lymphocytes 43%, monocytes 12%). The patient was discharged at the end of the third month, when he had been afebrile for three weeks.

Comment.—The enlargement of the glands, the blood picture, and the epistaxis were considered sufficient evidence, in the beginning, to allow a diagnosis of glandular fever. The titre of the Paul-Bunnell test was, however, not of diagnostic value. The melitensis infection was discovered subsequently only because local experience had taught the value of performing the appropriate bacteriological tests in all febrile patients in whom there was the slightest doubt about the diagnosis.

Case 2

A Maltese man aged 25 was admitted to hospital on June 3, 1946, with a provisional diagnosis of leukaemia. He had been ill for several weeks, and complained of vague febrile symptoms, weakness, and swellings of the neck. He was not severely ill and his temperature was 100° F. (37.8° C.). He looked pale but well nourished. The cervical, supraclavicular, epitrochlear, axillary, and inguinal glands were enlarged on both sides. They were firm, discrete, mobile, and non-tender, and were largest in the neck and axillae, where they measured up to 2 cm. in diameter. The tip of the spleen was palpable on deep inspiration but the liver was not enlarged. The blood picture was as follows: Hb, 70%; red cells, 3,650,000 per c.mm.; white cells 5,200 per c.mm. (polymorphs 45%, lymphocytes 45%, monocytes 10%—no abnormal cells present). The Paul-Bunnell test was negative. Low-grade fever continued and a tentative diagnosis of Hodgkin's disease was made.

A gland biopsy was arranged, but on the fifth day, before it was carried out, he had a rigor with high fever. At this time blood was taken for culture and the melitensis agglutination test. The latter was positive in a titre of 1 in 20,480, and after 17 days' incubation a profuse growth of *Br. melitensis* was obtained in the culture medium. During the next six weeks

there were three waves of fever before the temperature settled. The glands did not alter for two weeks; they then slowly decreased in size, and on discharge at the end of the ninth week only a few small nodes were palpable in the left posterior cervical triangle. At this time the spleen was not enlarged. Mild arthritis of the left knee developed but was not troublesome. Treatment was symptomatic.

Comment.—The anaemia, fever, lymphadenopathy, and splenomegaly suggested Hodgkin's disease. At first a diagnosis of brucellosis was not considered, and the melitensis infection was discovered, as in the previous case, by the application of routine tests.

Discussion

Conflicting statements appear in the literature about lymph-node involvement in brucellosis. McArthur (1939), in an important survey of the subject, made no reference to lymph glands. Musser (1938, quoted by Bloomfield, 1942) stated that general lymph-node swelling did not occur. On the other hand, Menefee and Poston (1938) found that lymphadenitis was often present. Avery (1942) noted that the glands were occasionally enlarged—either the cervical group alone or generalized.

Bloomfield (1942) consulted 191 unselected case reports and found specific mention of the lymph nodes in only 50—29 with enlargement and 21 without. In the 29 positive cases the distribution was as follows: cervical only, 13; generalized (superficial), 9; axillary only, 3; cervical and inguinal, 3; axillary and inguinal, 1.

As Bloomfield pointed out, the enlargement in many cases may have been merely incidental and not a specific manifestation of brucellosis. He was particularly doubtful about the cases with only localized involvement. In seeking evidence for the existence of a specific lymphadenopathy the important patients for scrutiny would seem to be those with generalized adenitis. This group consisted of nine cases, and further information about the glands during the course of the disease was given in only three. In one the swellings subsided about the fifth week and in another they persisted until the tenth month, when observation ended. The symptoms regressed rapidly in the third case and the [illegible] decreased in size within three days of admission; biopsy showed chronic lymphadenitis with necrotic foci, and *Br. suis* was isolated from the excised node. This patient died after multiple relapses, and the necropsy revealed generalized lymphadenitis of no specific histological type. *Br. suis* was recovered from many sites, including the lymph nodes. Gland biopsies were performed in two other patients; the lesion in one was "inflammatory," and the other served to exclude Hodgkin's disease and leukaemia.

Bloomfield concluded from his analysis of the nine patients with generalized adenitis that the lesion was probably specific for brucellosis in five, possibly in two, and of doubtful significance in two. No special aetiological importance could be attached to any single variety of Brucella—all three (*melitensis, abortus, suis*) were incriminated. Bloomfield added a case of his own which had enlargement of axillary, inguinal, and epitrochlear glands. Biopsy resulted in a histological diagnosis of lymphatic leukaemia, but the patient improved rapidly without therapy and the glands disappeared in the course of a year.

The generalized lymphadenopathy in both cases described above was without doubt a specific manifestation of brucellosis, the proof being the disappearance of the swellings as the general condition of the patients improved. Its occurrence in only two out of 42 cases suggests that it is not common.

The importance of the occasional occurrence of lymphadenitis in brucellosis is the confusion that it may cause in diagnosis. This point is well demonstrated by both of my cases. In Case 1 the clinical diagnosis of glandular fever seemed to be confirmed by the haematological examination. Wise (1943) drew attention to the fact that the study of the leucocytes in brucellosis frequently reveals abnormal cells suggestive of the early stage of glandular fever. Leys (1943) had two cases of abortus fever in which the monocyte count was so high that mononucleosis was considered as a possible diagnosis.

Rubenstein and Shaw (1944) stressed the clinical similarity which often exists between brucellosis and glandular fever. They pointed out that glandular enlargement was strongly in favour of the latter. Case 2 shows a superficial resemblance to Hodgkin's disease. Anaemia, splenomegaly, and lymphadenopathy may be common to both brucellosis and lymphadenoma, and the resemblance may be even closer in those cases of the latter which are characterized by the Pel-Ebstein type of fever. Parsons and Poston (1939) were of the opinion that in some cases of brucellosis even the histology of the lymph nodes may suggest Hodgkin's disease.

It is apparent that great advances are being made towards the goal of specific therapy for brucellosis (Spink, Hall, Schaffer, and Braude, 1949; Herrell and Barber, 1949). With the discovery of effective chemotherapeutic and antibiotic agents early diagnosis, previously of little moment, takes on a new importance. In such a protean disease diagnosis is notoriously difficult and clinical suspicion requires bacteriological confirmation. Mistakes arise when the physician, faced with a case of obscure pyrexia, does not suspect brucellosis. In areas where the disease is not common the error may be one of simple omission; but occasionally, as in the cases described above, the presence of an unusual clinical feature may cause such close resemblance to other conditions that the true diagnosis is obscured unless the specific bacteriological tests are employed. An awareness of the specific lymphadenopathy of brucellosis may prevent cases being wrongly diagnosed as glandular fever, lymphadenoma, or even leukaemia. A serious prognostic error may therefore be avoided and adequate therapy will not be withheld.

Summary

Two cases of melitensis fever in which generalized lymphadenopathy was a prominent feature are described. One case closely resembled glandular fever and the other simulated Hodgkin's disease.

The occurrence of specific lymphadenopathy in brucellosis is discussed and the difficulty in diagnosis which it may cause is stressed.

Lack of knowledge of this cause of lymphadenopathy may result in a serious prognostic error, and by delaying diagnosis may prevent the use of therapeutic measures at their most effective stage.

My thanks are due to the Director-General, Army Medical Services, for permission to publish this paper.

CLINICAL TRIALS OF SUCCINATES AND OF HEPARIN IN RHEUMATIC FEVER

BY

A. J. GLAZEBROOK, M.D., M.R.C.P.Ed.

Late Kirk Duncanson Research Fellow, Royal College of Physicians of Edinburgh

AND

FRED WRIGLEY, M.R.C.S., D.I.H., M.P.S.

Clinical Assistant, Department of Rheumatic Diseases, West London Hospital

The use of salicylates in the treatment of rheumatic fever is traditional. The therapeutic employment of this class of substances followed work originally described by Maclagan (1876). Many theories have been put forward to explain the action of salicylates, but no one has advanced a really tenable hypothesis. The subject has been reviewed and discussed from the biochemical, enzymatic, and clinical points of view by various authors (Glazebrook and Cookson, 1947; Wrigley, 1948).

Advances in the treatment of rheumatic fever have been concerned mainly with the dosage and route of administration of salicylates. It was with great interest, therefore, that we read of the work of Gubner and Szucs (1945), who drew attention to the therapeutic possibilities of succinates. Succinates act as catalysts in biological oxidation—for instance, in the metabolism of carbohydrates (Krebs, 1943) and of fatty acids (Breusch, 1943; Muñoz and Leloir, 1943). Gubner and Szucs suggest that during rheumatic fever there is an inactivation of various enzymes, and that the administration of succinates may prevent the inhibition of succinic dehydrogenase (cytochrome C reductase) and the inactivation of other respiratory enzymes. The administration of ascorbic acid and the use of the calcium salt of the succinate also seem to be indicated, because ascorbic acid and calcium enhance the activity of succinic dehydrogenase.

Gubner and Szucs's Results

Gubner and Szucs tested their theory by treating cases of rheumatic fever with sodium salicylate and sodium bicarbonate, sodium salicylate and ascorbic acid, sodium bicarbonate alone, sulphathiazole, penicillin, and calcium double salt of benzoic acid and succinic acid benzyl ester plus ascorbic acid. They found that penicillin, sulphathiazole, and sodium bicarbonate were useless, and that treatment with any one of them alone had to be discontinued after a few days because of the increased severity of the disease. A comparison of the cases treated by them with salicylates and with the succinate compound is given in Table I.

TABLE I.—*Comparison of the Therapeutic Effects of Salicylates and Succinate (Gubner and Szucs)*

	Type of Therapy	
	Salicylates (4·5 g. Daily)	Succinate (Average Dose 4·2 g. Daily). Ascorbic Acid (200 mg. Daily)
Total No. of cases	65	55
Period in hospital	52 days	34 days
Period on drug therapy	48 "	27 "
Incidence of drug toxicity	19%	2%
Duration of fever	13·5 days	5·7 days
Duration of leucocytosis	22 "	14 "
Duration of accelerated B.S.R.	43 "	24 "
Incidence of carditis	69%	19%
Incidence of relapse	7%	0%

No toxic symptoms were observed in the cases receiving succinate, except for flushing and slight mental confusion in one patient, and occasional nausea. Evidence accepted as indicating carditis included murmurs, gallop rhythm, pericarditis, and *x*-ray and electrocardiographic abnormalities. The figures indicate that the succinate compound is of considerable benefit and constitutes a great advance in the treatment of acute rheumatism.

Extension of this work was carried out by Szucs (1947), using a mixture of calcium salicylate and aspirin. The results claimed by him are shown in Table II.

TABLE II *(Szucs's Results)*

Type of Case	No. of Cases	Result
Osteoarthritis	208	Definite improvement in 95% within eight days
Acute infectious arthritis	17	All evidence of arthritic activity disappeared within ten days
Rheumatoid arthritis	27	22 cases showed definite improvement, with arrest of arthritic activity within an average of three months
Mixed arthritis	15	8 cases showed marked improvement, with complete or almost complete cessation of arthritic activity within an average of two months
Spondylitis	95	Improvement of variable degree in the majority
Rheumatic polyarthritis	34	All evidence of rheumatic activity disappeared within an average of 14 days

Most of the cases of rheumatoid arthritis were said to have previously received an adequate course of gold without definite improvement.

Present Investigation

In view of these published results we think it of interest to record our experiences in the treatment of acute rheumatic fever with: (*a*) calcium monobenzyl succinate, 10 gr. (0.65 g.) four-hourly, omitting night dose = 50 gr. (3.25 g.) daily; and (*b*) calcium double salt of benzoic acid and succinic acid benzyl ester, 10 gr. four-hourly, omitting night dose = 50 gr. daily; together with 200 mg. of ascorbic acid daily.

The calcium double salt of benzoic acid and succinic acid ester, together with ascorbic acid, was used to test the validity of the earlier claims of Gubner and Szucs, and their dosage recommendations were adopted. Calcium monobenzyl succinate was used because it presented a different form of the same essentials and might have been instructive from the point of view of treatment.

Anticoagulants

Glazebrook and Cookson (1947) have pointed out that substances benefiting acute rheumatic fever, rheumatoid arthritis, and anaphylactic states have a common action in that they are all anticoagulants—namely, salicylates in rheumatic fever, deep jaundice in rheumatoid arthritis, and heparin in anaphylactic states. On this basis they built up a theory that the curative effect of salicylate in rheumatic fever depended upon its power to prevent protoplasmic clotting and cell death precipitated by the irritation of intracellular antigen–antibody reactions.

This explanation of salicylate action rests on the unproved assumptions that rheumatic fever is a manifestation of allergy, and that protoplasmic clotting is the same process as blood-clotting and can be inhibited by the same anticoagulants. There is reason to suppose that Heilbrunn's (1943) work, showing a similarity between the mechanism of blood-clotting and of protoplasmic clotting, is not securely founded (Cookson, 1947—personal communication), while the hyaluronidase story of rheumatic fever (Guerra, 1946) is claiming increasing attention. However, these developments do not detract from the importance of

the work of Glazebrook and Cookson in drawing attention to the anticoagulant group of drugs.

Heparin is an inhibitor and salicylates may be inhibitors of hyaluronidase, and from its chemical constitution dicoumarol would seem very likely to be an inhibitor of hyaluronidase. It seemed to us, therefore, that there was a strong case for the use of heparin in acute rheumatic fever, and that good results might be expected because of either its anticoagulant properties or its inhibiting effect on the spreading factor, hyaluronidase. Wassen and Zander (1946) have reported good clinical results from the treatment of rheumatoid arthritis and of rheumatic fever with heparin and dicoumarol, and we have also recorded our experiences in the treatment of acute rheumatic fever with heparin (1,000 T.U. intravenously thrice daily) and salicylates (200 gr. (13 g.) daily in four-hourly doses). A control group was given salicylates, without heparin, and all three groups were also given 200 mg. of ascorbic acid daily. The results are set out in Table III.

A = Calcium monobenzyl succinate, 10 gr. 4-hourly.
B = Calcium double salt of benzoic acid and succinic acid benzyl ester, 10 gr. 4-hourly.

Most of the columns are self-explanatory. With regard to the presence of carditis, all cases having any suggestion whatever of cardiac involvement—e.g., a mitral systolic murmur without *x*-ray or electrocardiographic evidence of abnormality or other physical sign—have been so classified. It is possible that this definition of carditis has been too strict, and that some of the cases so designated would make good recoveries.

Discussion

It can be said at once that neither form of succinate compound used in this trial represented any advance on salicylate therapy. The duration of joint pains, of pyrexia, and of elevation of the blood sedimentation rate was much longer than in the salicylate-treated group. What is more to the point, Case 2 in the succinate group had succinate A without improvement, and then succinate B also without improvement. Finally, salicylates had to be given to terminate the pyrexia. Two other cases (Nos. 4 and 6) also did badly on succinates and showed great improvement immediately they were switched to salicylates. Evidence of carditis on follow-up was present in 50% of the cases, as compared with 40% in the salicylate-treated group, but not much importance can be attached to this, as the majority of cases had evidence of carditis on admission, before treatment had started.

We have not been able, therefore, to find any support for the contention of Gubner and Szucs that succinates given without salicylates improve cases of acute rheumatism. It will be noticed that in the second series of cases treated by Szucs calcium succinate was used together with aspirin. This we think strange in view of the apparently good results

in the first series of cases treated by a succinate compound without aspirin.

The calcium double salt of benzoic acid and succinic acid benzyl ester has also been used for the treatment of rheumatic fever by Wégria *et al.* (1948). They conclude that neither the natural course of the disease nor its signs and symptoms were modified by succinate therapy.

The group treated with heparin was very little different from the salicylate group when the duration of joint pains, of increased pyrexia, and of increased blood sedimentation rate is considered, although it does seem that the duration of pyrexia was less in the cases given heparin. The presence of carditis on follow-up was found in 62% of the cases given heparin, but in only 40% of the cases given salicylates. Practically all of the cases in the heparin-treated group had carditis on admission, before treatment with heparin had begun, but they had been given salicylates outside by their own doctors before coming under observation. As in the case of the succinates, therefore, not much importance can be attached to this finding.

It would seem from these studies that we have not yet found anything which represents an advance in therapy in the treatment of rheumatic fever. Nevertheless, although succinates are certainly not effective, as are salicylates, in cutting short the pyrexia of an acute rheumatic episode, there has been offered no proof in this paper that they are not an adjuvant to salicylate therapy. Until some method of administering heparin is found which will maintain a constant blood level without the necessity for repeated intravenous injections, a really satisfying trial of this product cannot be made.

Conclusions

Succinate compounds given with ascorbic acid in the dosage recommended by Gubner and Szucs are ineffective in the treatment of acute rheumatism. Heparin, in a dosage of 1,000 T.U. three times daily, does not significantly reduce the duration of episodes of acute rheumatic fever treated with salicylates.

One of us (A.J.G.) received a grant from the Royal College of Physicians of Edinburgh while this work was being carried out. We wish to thank Roche Products Limited for the ascorbic acid, and their Research Department for the calcium monobenzyl succinate, used in this study.

Dr. G. R. Wendt, chairman of the Psychology Department of the University of Rochester, U.S.A., is recently reported to have said that because a serious amount of charlatanism has developed in the U.S.A. it is essential that all groups concerned with the mental health movement should collaborate to protect the public through legislation (*New York Times*, September 11, 1949). Dr. Wendt considers that it is the primary responsibility of the medical profession to take the initiative in working for the protection of the public. He decried the almost complete lack of mental health legislation in the U.S.A. despite the great need for it. Only in Kentucky is there a law making it mandatory for each psychologist to get a licence before he can conduct private practice.

SUBACUTE POISONING BY THALLIUM TREATED WITH BAL

BY

EGIDIO S. MAZZEI, M.D.
Professor of Clinical Medicine

AND

FIDEL SCHAPOSNIK, M.D.
Assistant
Department of Medicine, Medical School, University of La Plata, Argentina

In our paper on a fatal case of subacute thalliotoxicosis (Mazzei, Schaposnik, and Pedace, 1948a) we emphasized the basic clinical characters of acute, subacute, and chronic poisoning by thallium, together with the micropathology of each. The present paper deals with another case of poisoning by thallium—a suicidal attempt—which was successfully treated with BAL.

Though there does not seem to be any clinical experience with this drug in this type of poisoning, we decided to try it. Afterwards, Furmanski (1948) explained the beneficial action of BAL in poisoning by thallium. He used the drug with favourable results in severe peripheral neuropathies which had proved intractable to large doses of vitamins and crude liver extract. He based the treatment on the accepted view that such neuropathies are caused by the inactivation of the enzymatic systems of the nerve cells by toxins or toxic metabolites. He thought that BAL acted in these cases in a similar way to that in metal poisoning—i.e., by combining itself with the toxic metabolites after setting free those enzymes vitally related to cell respiration.

With these facts in mind, we thought that in human cases of poisoning by thallium BAL could be of use by displacing and then eliminating the metal already combined with protein enzymes of the nervous cells.

Dosage and Toxic Disorders

In the light of Eagle's wide experience, the Council of Pharmacy and Chemistry of the American Medical Association suggests the following outline of dosage in arsenical poisoning; this outline can be extended to poisoning by other metals.

In severe arsenical reactions.—First and second day, six daily injections of the drug, each of 3 mg. per kg. of body weight. Third day, four injections of the same dose. During the following 10 days or until full recovery is attained, two daily injections.

In reactions of medium severity.—Each injection should consist of 2.5 mg. per kg. of body weight. During the first two days four doses should be given, two on the third day, and one during the following 10 days or until full recovery.

In our case we used approximately the medium-severity doses, the total amount of drug injected being 3.1 g.

The administration of BAL may give rise to some unpleasant though transient effects. In view of its affinity for heavy metals, some of the toxic disorders following the use of high doses can be attributed to its combination with the metals which form part of the molecule of certain enzymes (copper, zinc, iron, and manganese). The removal of the heavy metals renders inactive the corresponding enzymes by depriving them of their protein groups (Furmanski, 1948). This theory seems to be supported by the drop in the magnesium content of the blood and disruption of the calcium/magnesium balance seen in patients receiving BAL, thus giving rise to the characteristic

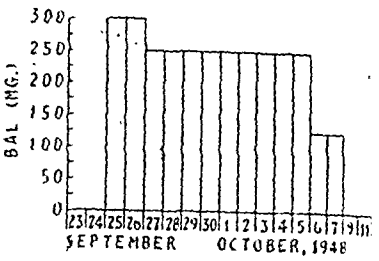
symptoms of tetany. However, the enzymatic inhibition is rapidly reversible, so the accident does not seem to have undue importance.

The most common toxic symptoms are excessive salivation, vomiting, lacrimation, sweating, generalized myalgias, headaches, severe fleeting pains at the site of the injection, tachycardia, increased blood pressure, dyspnoea, and precordial constriction.

We must call attention to the high levels of the blood pressure in our patient. Though thalliotoxicosis is often accompanied by high blood pressure—especially the diastolic—the rise was evidently coincident with the course of BAL; it must therefore be attributed, partly at least, to the action of the drug.

Case Report

The patient, an Argentine girl aged 16, was a student at a secondary school, and lived in La Plata, province of Buenos Aires. During the three days September 16–18, 1948, she swallowed approximately 34 g. of the rat-poison paste "zelio," which contains 2% of thallium sulphate. On September 20 she began to feel skin hyperaesthesia and pains in the muscles of her lower limbs. On the following day her temperature rose to 38° C. (100.4° F.) and the myalgias had become very severe. The mere touch of the bedclothes caused violent pains, and she became progressively unable to use her legs.



On September 20 one of us was called in to see her. The temperature was 40° C. (104° F.). She was restless, with facies dolorosa, of asthenic habitus, and was lying on her back because of severe pain in her feet and legs, which was greatly intensified by the slightest touch or movement. She was undernourished, with small amount of subcutaneous fat. Her skin was hot and dry. The shape and reflexes of the pupils were normal. Her pulse was rhythmic, 84 a minute; blood pressure 170/120 mm. Hg. On palpation the whole of the abdomen was tender. The liver and spleen were within normal limits; the renal areas were painful. She was completely unable to move her lower limbs, and passive mobilization caused intense pain, particularly in the feet. The severe hyperalgesia made it impossible to carry out a thorough examination. The Achilles-tendon, patellar, and abductor reflexes were increased.

A psychiatric examination was performed by Dr. Alejandro Resús, who reported: "Her mental picture is prior to her attempt at poisoning, and must be the determining factor of the same. The symptoms correspond to the development of a constitutional and atypical exacerbation, which is due to the overlapping of the emotional psychasthenic and schizoid components (hypermotivity, erythrophobia, exaggerated psychomotor reactions; varied neurotic tendencies, phobias, and certain obsessions; a tendency to introversion and isolation, ideo-affective disassociation of personality)."

Laboratory Tests.—Blood count: red cells, 4,789,000; Hb, 95%; platelets, 240,000; white cells, 6,400 (neutrophils 60%, eosinophils 0.66%, monocytes 13%). Coagulation time: five minutes; bleeding time: two minutes. Sedimentation rate: first hour, 15 mm.; second hour, 38 mm. Blood urea, 30 mg. per 100 ml.; blood sugar, 96 mg. per 100 ml; blood cholesterol, 180 mg. per 100 ml.; alkali reserve, 50 vols. %; chloride in cells, 1.56 mg. per 100 ml.; chloride in plasma, 264 mg. per 100 ml.; blood proteins, 8.28 g. per 100 ml. (serum albumin, 4.82 g.; serum globulin, 3.46 g.). Urine: turbid; acid reaction; slight sedimentation; specific gravity 1009; ammonia 0.47 g., urea 13.1 g., chlorides 2.2 g., phosphates 1.3 g., albumin 1.5 g. per litre; no sugar, acetone, or bile pigment. The sediment showed granular and hyaline casts, some red cells, and a large number of desquamation cells.

Treatment and Progress

On September 23 treatment was started with sedatives, analgesics, 25% glucose solution intravenously, vitamin B complex, and 15% magnesium sulphate with 0.05 g. of papaverine intramuscularly. Two days later the first phials of BAL from an English firm were obtained. During the first two days 300 mg. was injected daily. After this the treatment was continued with the same product, but of American origin (10% solution). A total of 3.1 g. was given (see Chart).

Throughout the administration of the drug the patient developed a morbilliform exanthema of varying degrees in the upper limbs, neck, and chest. Each injection of BAL gave rise to intense headaches and greatly increased the pains in the lower limbs; opiates were partially successful in alleviating these conditions. Weekly estimations of the urine showed considerable fluctuations in the albumin content (between 0.2 and 1.5 g.); albumin, together with renal elements, finally disappeared in February, 1949.

A few days after treatment was suspended the pains in the lower limbs began to decrease, and by December, 1948, the patient was free from them. The muscles of the thighs and legs gradually recovered their original tone and size with the help of massage. The hair on the head began to fall on October 5, and within a few days only a few patches of short hair remained.

For three months the patient was treated in a private mental institution. Insulin shock brought about a definite improvement in her psychic manifestations; moreover, her weight increased by 7 kg. (15 lb. 7 oz.). During this period massage was continued until total recovery. The last examination (April, 1949) showed that she had completely recovered.

Summary

A case of subacute thalliotoxicosis caused by swallowing 45 g. of a rat-killer paste containing 2% thallium sulphate is described. A total of 2.85 g. of BAL was given in the course of 13 days. The patient fully recovered.

The pharmacology of the drug is described, together with the reasons for using it in poisoning by thallium.

The need for new legislation for the prevention of smoke was the principal theme discussed on September 29 at the conference of the National Smoke Abatement Society in Harrogate. Reports of the limited success and difficulties of several local authorities in administering new local Acts of Parliament emphasized the form that new laws must take if they are to be effective in preventing, rather than just abating, smoke. Strong criticism of the opposition of "big industry" to a new Parliamentary Act obtained by the city of Birmingham, which had led to a serious weakening of its smoke clauses, was made by Dr. W. R. Martine, Senior Assistant Medical Officer of Health. In contrast, an officer of the Smoke Control District of Los Angeles, who was present as a visitor to the conference, described the effective and far more stringent regulations imposed in California and many American cities. Dr. Metcalfe Brown, hon. secretary of the Manchester and District Regional Smoke Abatement Committee, reported on an investigation in the Carrington area, near Manchester, where one of the country's biggest power stations is being erected, and other industries are causing concern. Local authorities around the area are co-operating in running a network of instruments, extending over 36 square miles, to measure the pollution of the air for comparison with conditions when the power station is operating. In conjunction with this a survey on the effects of smoke and fumes on plant life—an important matter for farmers—is being conducted jointly by the Smoke Abatement Committee, the Department of Botany of Manchester University, and the Agricultural Research Council.

FATAL BRONCHOSPASMODIC CRISIS COMPLICATING MILIARY TUBERCULOSIS OF LUNGS

BY

T. A. BRAND, M.D., Ch.B., D.C.H.
Registrar

AND

JOHN BURKINSHAW, M.B., M.R.C.P.
First Assistant
Paediatric Department, St. George's Hospital

In a recent case of miliary tuberculosis attacks of severe dyspnoea associated with slowing of the pulse developed during streptomycin treatment. These attacks ultimately proved fatal, and as no similar occurrence appears to have been reported it seems worth while to record the symptoms and findings.

Case Report

The patient, a boy aged 11 years 9 months, had no record of serious illness and enjoyed normal health until March, 1948, when he was admitted into another hospital with a severe upper respiratory infection associated with general listlessness, anorexia, and cough. Clinical examination showed no abnormality in the chest, but radiographs revealed a shadow in the right mid-zone, which subsequently cleared. Mantoux reactions in dilutions of 1 in 10,000 and 1 in 1,000 were negative at this time. As his progress was slow he was sent to an open-air school, from which he returned at the end of July acutely ill, with a high fever and a left-sided pleural effusion. It was not until November that there was radiological evidence of miliary tuberculosis in the lungs. He was then transferred to the Victoria Hospital for Children for streptomycin therapy. No history of contact with a case of tuberculous infection was traceable in his family or companions. There was no personal or family history of asthma, hay-fever, or urticarial eruptions.

On admission (November 7, 1948) the clinical diagnosis of miliary tuberculosis with a large left-sided pleural effusion was confirmed radiologically. The Mantoux test was strongly positive with the 1 in 1,000 dilution. He had a low-grade pyrexia, and the pulse rate was 112–120 a minute. The spleen was not enlarged and no lymph glands could be felt in his neck or elsewhere. The urine showed a trace of albumin and a few casts, but no red cells. The cerebrospinal fluid remained normal throughout the illness. Despite frequent examinations tubercle bacilli were not isolated from sputum, laryngeal swab, or stomach washings.

The patient was given a three-months course of intramuscular streptomycin, with a total dosage of 77.9 g. At the end of the course, 13 days before his death, his lung condition showed both clinical and radiological improvement with resorption of the effusion. There was thickening of the left pleura and some coalescence of the miliary shadows in the right upper lobe, especially towards the hilum. No abnormality was found in the nervous system. He had a slight unproductive cough, and his weight was stationary at 57 lb. (25.65 kg.). His general condition was slightly better than on admission.

On February 12, 1949, he developed a mild coryza with some increase of the cough. Next day at noon he was seized with a bad attack of dyspnoea associated with severe apprehension and very laboured but ineffective expiration. He vomited a large quantity of mucus with some purulent-looking material, and in the course of an hour the attack gradually passed off. Scattered rhonchi and medium rales were audible over the chest, but there was no fever.

At 7 p.m. the same day a second attack occurred. On this occasion cyanosis was pronounced, and it was noticed that the pulse rate had dropped to 80 a minute. He had great difficulty in expelling air from his chest, so that expiration lasted three to four seconds—about twice as long as inspiration. This attack was relieved by a subcutaneous injection of 8 min. (0.5 ml.) of 1 in 1,000 adrenaline and by oxygen inhalation. After the attack had passed off the pulse rate was recorded at 120–142 a minute.

For 36 hours he remained free of dyspnoea and showed no abnormality except for persistent tachycardia 120–136 and a few scattered medium rhonchi on lung auscultation. On February 15 he had two more attacks, with intense expiratory dyspnoea and slowing of the pulse to 80 a minute. During both of these he lost consciousness for a few minutes.

On February 16, at 9 a.m., he had a very severe attack which lasted an hour. This time the expiratory difficulty was very great and the pulse fell to 68 a minute, though the volume was remarkably good. He became unconscious and was deeply cyanosed for 45 minutes, during which time he was given 1 min. (0.06 ml.) of 1 in 1,000 adrenaline subcutaneously at minute intervals and continuous oxygen inhalation through a glass funnel. Examination of the chest at this time, as during preceding attacks, showed no evidence of pneumothorax. The high-pitched rhonchi usually associated with bronchospasm were not heard during this attack—a remarkable finding in view of the intensity of the expiratory effort. After 45 minutes the pulse rate rose abruptly to 168 a minute and the spasm passed off, consciousness returning during the next 15 minutes. At this stage direct examination of the larynx showed no evidence of spasm of the cords. The patient was then nursed in an oxygen tent, where he regained and maintained a good colour, was quite cheerful, and ate a normal tea and supper. Examination of the chest now showed scattered rhonchi, with some medium rales in the right upper lobe. The temperature was normal and the pulse between 148 and 160, but of good volume. At 1 a.m. on February 17 he suddenly became restless, urgently dyspnoeic, and cyanosed, struggled into a sitting position, and in two to three minutes collapsed and died.

Post-mortem Findings:—Necropsy was carried out by Professor T. Crawford 13 hours after death; the following significant findings are extracted from his report.

"*Respiratory System*:—Dense pleural adhesions are present over the lateral aspect of the left lung, and the appearance suggests an organizing caseous exudate at this area. The trachea appears normal, but both bronchi are pressed upon by enlarged caseous glands surrounding them close to their origins. There is, however, no ulceration of the glands into the bronchi. An irregular caseous focus measuring 2 by 1 cm. is situated in the lower part of the upper lobe of the left lung, and around this there is an area of caseous bronchopneumonia. Three small caseous foci measuring 5 mm. in diameter are present in the right upper lobe. Small miliary lesions, just visible to the naked eye, are scattered widely through the lung tissue. The *spleen* is moderately enlarged and shows a few small tubercles in its capsule and scattered through the substance. *Lymphatic System*:—Enlarged and caseous glands are present at the hila of both lungs and beneath the bifurcation of the trachea. Further glands are present in chains extending up the sides of the trachea into the anterior triangle of the neck, and at this site both vagus nerves are firmly adherent to caseous glands. Caseous glands are also present in the portal fissure and beside the abdominal aorta. *Head*:—The brain and meninges appear normal and show no evidence of tuberculosis. *Summary*:—Primary tuberculosis of the lung; tuberculosis of mediastinal, cervical, and abdominal lymph glands with involvement of the vagus nerves; miliary tuberculosis."

Comment

Correlation of the clinical and post-mortem findings in this case suggests that the attacks of severe expiratory dyspnoea associated with slowing of the pulse and evidence of bronchospasm resulted from vagal stimulation. The vagus nerves were found adherent to caseous lymph glands, and it is suggested that the attacks were initiated by change of position affecting the adherent nerves.

Our thanks are due to Dr. Charles Pinckney for permission to publish the case and to Professor T. Crawford for his post-mortem report and for helpful advice and criticism.

Medical Memorandum

Spontaneous Disappearance of Apparently Secondary Growths in Liver

The following case contains several points of interest, particularly the finding of three apparently secondary nodules of some size in the liver during the removal of a huge adenocarcinoma of the left ovary, and the fact that they had disappeared when sought at operation two and a half years later.

Case Report

A farmer's wife aged 58 complained on September 8, 1938, of increasing size of the abdomen for six months, with some generalized pain, a dry cough, and, latterly, much dyspnoea. There had been occasional vomiting; the appetite was poor, the bowels regular. She did not think she had lost weight. For the past month she had had palpitations and swelling of the feet. There had been three normal pregnancies, and her periods had been regular until 52. Since then she had had small losses of blood at long intervals.

She was a pale, thin woman, markedly dyspnoeic; tongue clean, pulse 100/110, apex beat displaced to left, heart sounds clear, B.P. 140/90. Right chest stony dull to level of scapular spine; no adventitious sounds. Left side clear. Enormous tender regular swelling, filling abdomen, some free fluid. Small normal cervix; uterine body not felt apart from abdominal swelling. Diagnosis: a malignant cyst of ovary, unlikely to be operable.

Admitted to Royal Sussex County Hospital on September 21. Next day 31 oz. (880 ml.) of clear fluid aspirated. A radiograph showed no sign of secondary growth of lung or pleura. During the next 18 days four further aspirations averaged 38 oz. (1.08 litres). After each a radiograph was negative to growth or tuberculosis. The pleural fluid was sterile on culture. Film: polymorphs 68%, lymphocytes 30%. R.B.C., 4,100,000; Hb, 65%; C.I., 0.8; W.B.C., 11,000 (P. 77%, L. 14%, E. 2%, M. 7%). Wassermann test not done.

In view of the persistently negative *x*-ray reports for secondaries in the chest it was decided to give her an outside chance and to operate.

Operation, October 11, 1938.—Under bromethol, cyclopropane and oxygen a long paramedian incision exposed a huge left ovarian cyst, softened and necrotic in many places. A thinned-out ribbon of transverse colon was stretched across it. This and many adhesions of small intestine and omentum were separated by gauze dissection and the cyst removed: several leaks of dirty fluid and necrotic material occurred from the cyst. An apparently healthy right ovary was also removed. Three firm raised nodules, roughly 1–1½ in. (2.5–3.75 cm.) in diameter, present on the anterior surface of the right lobe of the liver, were regarded as certainly secondary growths from the malignant ovary, and for this reason, as well as the patient's poor condition, panhysterectomy of a small smooth uterus was not done.

Pathological Report.—Left ovary, a malignant papillary adenocarcinoma; right ovary, post-menopausal changes. No sign of malignancy.

The patient made a good recovery and was discharged on November 2, with a poor prognosis. During the ensuing months no further fluid collected in the right pleura and signs of pleural thickening gradually disappeared. A year later the liver was not enlarged and there was no evidence of secondaries or fluid in the abdomen. The patient felt well and had put on weight. This unexpected result was maintained throughout the second year after operation.

On March 21, 1941, however, she returned. For six months she had had small losses of blood per vaginam, with a watery discharge in the evenings, and felt tired. The abdomen and liver showed nothing abnormal: P.V., a small, firm mass, which bled on touch, protruded from the cervix and there was some thickening of the lower uterine segment. Biopsy showed the protruding mass to be adenocarcinomatous.

Second Operation.—After a few days' douching and a transfusion of 1 pint (568 ml.) of blood, operation was performed on March 25. The abdomen was opened through the old scar and the liver first examined. The only sign of the three previous nodules was a small puckered scar; the rest of the liver surface was smooth. The caecum and some coils of ileum were adherent to the uterus, and after separating these panhysterectomy was done. The lower uterine segment was much thickened and the parametrium very vascular. On detaching the former the uterine body tore away, leaving the lower uterine segment and cervix almost completely replaced by soft growth, which was already infiltrating the parametrium. There was little hope of their complete removal. It was decided to drain the canal into the vagina and to apply radium later. The abdomen was closed and 2 pints (1.4 litres) of blood given by drip. She made a satisfactory recovery and the vaginal tube was removed on the fourth day.

Two and a half weeks later radium was given—20 mg. in the cervix and a 25-mg. tube in each vaginal vault for 15 hours (1,050 mg.-hours). Another application followed three weeks later—10 mg. cervical and two 25 mg. vaginal for 15 hours (900 mg.-hours). Total for the two applications, 1,950 mg.-hours. On March 10 the patient was discharged.

In September there was a suspicion of thickening along the right utero-sacral ligament, but three months later this had disappeared and the tiny cervix was mobile. At this date the patient complained of pain in the spine at mid-dorsal level. Movements were good and a radiograph showed no sign of secondary growth. In January, 1942, this pain had gone, but another had taken its place in the lower lumbar spine. Radiographs revealed no secondary growth, but some osteo-arthritis.

In December, 1948, the patient was able to do her housework, and only the headaches and back pain bothered her. She then weighed 2 st. (12.7 kg.) more than just after her first operation.

Comment

The special point of interest is the proved disappearance, two and a half years after the removal of a malignant ovarian cyst, of three apparent secondaries in the liver. In the absence of a biopsy, however, no certain claim can be made that they were malignant. A second point is that no further growth in the peritoneal cavity ensued. Thirdly, the disappearance of all growth from the remains of the lower uterine segment and parametrium after a moderate dose of radium was hardly expected.

The three incidents together suggest not only a low grade of malignancy but an unusual degree of bodily resistance to cancer. A risk was admittedly taken in using radium with so slender a barrier between the remains of growth and the peritoneal contents.

The presence of a large pleural effusion accompanying malignant cysts does not necessarily imply metastases, as malignant growths of the ovary seldom metastasize outside the peritoneal cavity. The connexion between the occasional post-menopausal losses over six years and the malignant ovary is speculative. A certain number of such tumours do seem to provide an oestrogenic hormone which re-energizes the endometrium after the menopause. The adenocarcinoma of the uterus was almost certainly a spread from the ovary, and emphasizes the importance, whenever feasible, of doing a panhysterectomy as well as a double ovario-salpingectomy in such cases.

A TEXTBOOK ON TRANSFUSION

Blood Transfusion. Edited by Geoffrey Keynes, M.A., M.D., F.R.C.S. (Pp. 574; 110 illustrations. £2 12s. 6d.) Bristol: John Wright and Sons. 1949.

The great amount of work carried out upon all aspects of blood transfusion during the past decade has created many opportunities for new books. The perspective has altered completely since 1939, when Riddell wrote the last major British textbook on transfusion. For example, Riddell speculated on the possibility that incompatibility within the MN system might be the cause of minor haemolytic reactions, but there are now numerous investigators who know from their own experience that these groups are of negligible clinical importance.

This new textbook is a comprehensive guide to the whole subject. It begins with a delightful and authoritative account of the history of blood transfusion, by Mr. Geoffrey Keynes. The indications for, and complications of, transfusion are discussed at length by Dr. Bodley Scott. Mr. A. Till writes on technique, and Dr. H. F. Brewer on blood groups, the organization of a hospital transfusion service, and, with Mr. F. W. Mills, on the blood donor. There is a chapter about transfusion in infancy by Professor R. W. B. Ellis, an account of blood storage by Sir Lionel Whitby, and a particularly lucid and thorough chapter on blood derivatives and substitutes by Dr. R. I. N. Greaves.

It is natural that in a book of this size and scope, written by a number of different authors, there should be signs of unevenness. For example, almost a page is devoted to a description of the rare antigen C^w, which is of very small importance in blood transfusion. By contrast, a reader wanting to know how old a bottle of stored blood can profitably be given to an anaemic patient must be content with brief, conflicting dicta appearing in different sections of the book. On page 84 he is told that "for the relief of chronic anaemia . . . stored blood *should not be used*"; *but he must somehow try to reconcile* this with the statement on page 459 that "blood . . . stored for a period of 14 to 21 days is almost as good as fresh blood for the treatment of simple anaemia." If the reader were given some quantitative data on the survival of erythrocytes stored for different periods in acid citrate-glucose solutions he could judge for himself which of these two statements is the more reasonable. A certain number of fallacies, derived from other authors, have found their way into the book. For example, it is said in connexion with transfusions to infants with haemolytic disease that if the red cell count is raised above a certain level (*3.5 million/c.mm.), the excess red cells will be lysed.* This concept is unquestionably incorrect. A second example is a formula given for calculating the amount of blood to transfuse to an infant. This assumes a blood volume of 110 ml./kg., but, except in plethoric infants, who are unlikely candidates for transfusion, the blood volume is in fact approximately 75 ml./kg.

These and other occasional lapses make one hesitate to describe the whole book as authoritative, though there is no doubt that large sections of it deserve that title. In any case its wide scope and discriminating lists of references will ensure its value to all who practise blood transfusion.

P. L. MOLLISON.

INVESTIGATION OF THE RENAL TRACT

Cystoscopy and Urography. By Jas. B. Macalpine, F.R.C.S. Third edition. (Pp. 570; 338 illustrations and 15 coloured plates. £3 3s.) Bristol: John Wright and Sons. 1949.

The second edition of this well-known work was a war casualty. All the copies of that edition and the materials for a reprint were destroyed by bombs, so that the book was unobtainable for many years. The only benefit that accrued from the misfortune was the time afforded the author to bring it up to date.

The chapter on urinary tuberculosis has been largely rewritten and a new section on its pathology has been added. Cystoscopy is only one of the steps in the routine investigation of a urological case, and the findings must be correlated with other methods of obtaining information. The author has therefore done well in not confining his attention to cystoscopy and posterior urethroscopy. This allows consideration of other questions—whether, for instance, the rapid secretion of radio-opaque dye and a dense shadow of an apparently normal pelvis is sufficient guarantee that the kidney on that side is free from tuberculous infection. It is well known that there are two schools of thought on this subject, some urologists insisting on catheterization of the ureters and others relying on the cystoscopic and pyeloscopic findings. Mr. Macalpine favours an intermediate course. He "accepts the urographic evidence of disease in the principally affected kidney and gives due weight to the pyelogram of the other side." He recommends that cystoscopy be limited to a quick inspection of the bladder and an indigo carmine test, the danger of producing a secondary infection being thereby reduced. The least satisfactory paragraphs are those describing the endoscopic resection of the prostate. Here the author relies more on the writing of others than on his own experience and there is a loss of that personal touch which characterizes the rest of the book. A new section on the punch-operation for prostatic hypertrophy by means of the technique used at the Mayo Clinic has been contributed by Mr. R. H. O. B. Robinson.

This book established itself as the best English work on this subject long ago, and the new edition should more than maintain its previous reputation. It is clearly written, practical in its outlook, and the illustrations and coloured plates are excellent.

KENNETH WALKER.

CHEMISTRY OF ALKALOIDS

The Plant Alkaloids. By Thomas Anderson Henry, D.Sc.(Lond.). Fourth edition. (Pp. 804. £3 3s.) London: J. and A. Churchill. 1949.

Everyone interested in plant alkaloids, whether botanist, chemist, or pharmacologist, owes a great debt of gratitude to Dr. Henry for the way in which, at intervals of about ten years, he has brought his book up to date. At its first appearance in 1913 it was a substantial volume of some 480 pages. Each successive edition incorporated much new material, and the present contains something like three to four times the number of words as the original volume. Apart from a description of the purine alkaloids which was omitted from the second edition, the introduction of new material has not involved jettisoning the old, and the present book is probably the most authoritative and exhaustive work on the plant alkaloids that has ever been written.

Those who have used this book for many years—and there must be many who have the first, second, and third editions on their shelves—will be pleased to find in the new volume all the valued features of its predecessors. The botanical origin of groups of alkaloids is discussed as carefully as ever and has been brought up to date. The sections giving an account of the pharmacology of the alkaloids are admirable, some of them have been considerably enlarged, and the synthetic substitutes for natural alkaloids have been briefly but adequately described. Indeed, these sections provide as good an introduction to the relevant literature as can be found.

The main bulk of the book is concerned with the chemistry of the alkaloids, in particular with the difficult structural problems presented by these fascinating natural products. Dr. Henry is here a master of his subject. Full justice is done to all relevant research, but the reader is never weighed down by the immense mass of experimental evidence, because the author guides him skilfully through intricate argument and counter-argument and illuminates his path with innumerable structural formulae. The narrative is made vivid by the inclusion of small practical details, such as the experimental conditions of many reactions and the physical constants, crystalline appearance, and solubilities of innumerable substances. It is probably this feature which has made earlier editions so

popular among alkaloid chemists. Dr. Henry has always kept close to experimental details, so that in this comprehensive work he has found space to remark that strychninolone crystallizes in "glistening prisms" and berberal in "colourless glancing leaflets." He has the delight of the craftsman in his subject; just as the carpenter caresses a fine piece of wood with his hands, so Dr. Henry's pen cannot resist a tribute to a beautifully crystalline substance.

A final word must be given about the reference lists which are distributed throughout the work. In many years' use of earlier editions I have never found a reference inaccurately quoted, and study of one or two lists in the present edition has shown no important reference to be omitted.

H. R. Ing.

MONOGRAPH ON RHEUMATISM

Manuel Pratique de Rhumatologie. By Professor Gunnar Kahlmeter. (Pp. 134; illustrated. No price). Paris: Expansion Scientifique Française (23, Rue du Cherche-Midi).

Many English readers will welcome this French translation of Kahlmeter's manual of the rheumatic diseases. They will find a simple and unpretentious little book, written with a brilliant power of clinical exposition and lucid argument. There are no references, for this is Kahlmeter's thought and experience; there is no index, for this is a book to read, not a work of reference.

The important chapters are those on acute rheumatism and rheumatoid arthritis. The author regards them as closely related conditions, and argues the matter so well as to be almost convincing. Discussing the aetiology of rheumatoid arthritis, he inclines to the hypothesis of "allergy," but by this he means a specific mode of reaction to a number of causal agents. "Lorsque, dans la théorie allergique moderne," he writes, "on fait usage du mot *allergie*, ce mot doit être pris, non dans sons sens original, mais plutôt dans celui de 'mode spécifique de réaction.'" *This simply will not do. It is as if a chemist* should write, "Sodium chloride is to be taken as meaning anything with a salty taste." Allergy has a precise meaning, which is not "a specific mode of reaction," and it is not open to Professor Kahlmeter or anyone else to tamper with the meaning of scientific terminology.

There are concise descriptions of "infective pseudo-rheumatism" (the nomenclature throughout is that most familiar to French readers); of osteoarthritis; of spondylitis; of rheumatism of the menopause; of tendinitis and bursitis; and a less satisfactory chapter on myalgia.

The author's experience in therapeutics is of particular interest. It is refreshing to find due attention given to medicinal measures, for we in this country rely far too much on physiotherapy, but it is surprising to read that the author has found colchicine of value in rheumatoid arthritis and in rheumatism of the menopause. After reading his warm advocacy of *x*-ray therapy in rheumatoid arthritis, bursitis of the shoulder, and tendinitis, especially that associated with osteoarthritis of the hip and knee, English readers may feel that a more extended trial of the method should be made in this country.

Kenneth Stone.

Dr. Lowmain E. McCrea's *Clinical Urology* (second edition; pp. 503; 265 illustrations, 7 in colour; $6.50; Philadelphia: F. A. Davis Company, 1948) is an excellent book, and the first edition, which appeared in 1946, met with great success. It is written for practitioners, and its object is to tell them what the diagnosis is likely to be, how the patient should be treated, and the best means of carrying out this treatment. Not a word is wasted, and when words can be reduced in number by the use of an illustration the illustration is provided. The plates and diagrams are of high standard, and merely by looking at them a tired general practitioner at the end of a long day's work could obtain a good knowledge of urology. A book which lays down rather than discusses methods of treatment must necessarily be dogmatic, but dogmatism here is not obtrusive; the author only states that the methods he prescribes are those that have given the best results in his own experience. It is perhaps necessary to add that the paper, the printing, and the general production are such as one would expect from a country where publishers have not been handicapped by the austerities produced by the war.

A CHOLERA CENTENARY

BY

MAJOR GREENWOOD, D.Sc., F.R.C.P., F.R.S.

More than 270 years ago Sydenham predicted that the epidemic diseases which he saw would give place to others the nature of which it was impossible to foresee. He was writing some ten years after the last epidemic of plague on a grand scale in Great Britain. Just a hundred years ago our great-grandfathers, to whom plague was a distant memory, suffered the second epidemic of Asiatic cholera, which has not afflicted us since 1866. In London the worst week was that ending September 8, 1849, with 2,021 deaths; four weeks later the total had sunk to 288, and the epidemic rapidly declined. It killed more than 50,000 persons in England and Wales—about as many as the war in the air of our time. Now we study with a certain anxiety the much smaller figures of notified poliomyelitis; with a certain anxiety because, epidemiologically speaking, we do not know so *very* much more about it than our great-grandparents knew about cholera. Sydenham was a good prophet. The cholera of 1849 was the subject of three bulky reports, by the General Board of Health, by the College of Physicians, and by the General Register Office. Copies of them, even those in an epidemiological department, need to be handled cautiously in these days of soap-rationing; they are apt to be very dusty. That published by the College of Physicians is the most readable because it is not very statistical and is the work of a single author, William Baly (1814–61), a physician of sufficient importance to be remembered by D.N.B., but hardly even a name to most of us.

William Baly, a student at University College and Bart's, graduated M.D. at Berlin in 1836, became physician to the Millbank Penitentiary in 1841, and F.R.C.P. in 1846; he was thought to be a rising man, and was appointed physician to the Queen, as understudy to Sir James Clark, in 1859. He was killed in a railway accident when 47. His report is quite readable and strictly orthodox, as the official report of a professional body is sure to be. A reader in 1949 may say that, generally speaking, when Baly was quite sure, he was quite wrong, and when he doubted he inclined to the wrong side. That, however, is a grossly unjust way of judging an official report made by a young man a hundred years ago. We are children of our age, deserve blame if, intellectually and morally, we are behind it, but certainly none if we fail to anticipate future discoveries.

In 1849 Galenical epidemiology was well stricken in years but still vigorous: Southwood Smith (1788–1861) and John Sutherland (1808–91), two of our best practical epidemiologists, were Galenists in the sense that the epidemiological importance of tainted air, of miasma, was to them much greater than that of contagion. There was indeed then living one man, Jakob Henle (1809–85) who published in 1840 in his pathological researches a remarkable essay on miasmas and contagions (it was reprinted, in Sudhoff's series of Klassiker der Medizin, in 1910) which Baly might have read. Henle's argument was, briefly, this: that while in ancient medicine most epidemic diseases were reckoned to be miasmatic, now—viz., in 1840—only one, malaria, would be universally regarded as purely miasmatic; three—syphilis, scabies, and hydrophobia—would be classed as purely contagious. All the others—smallpox, measles, cholera, etc.—he classified as miasmatic-contagious, but very plainly indicated his opinion that the emphasis should be on the contagious side. He then—as had Fracastorius (1483–1553) nearly 300 years before—put forward the idea of a living contagion, perhaps a minute vegetable organism, as the specific biological cause of each disease and, more fortunate than Fracastorius, could point to a striking analogy, the epidemic disease of silkworms—muscardine—which had been proved by Bassi and Audouin, a few years before he wrote, to be due to a vegetable parasite. But Henle could not *demonstrate* any such *contagium vivum* in connexion with human epidemic diseases, excluding scabies.

Baly does not mention Henle, but he does speak of John Snow (1813–58), who had already urged that cholera was a water-borne disease, and, quite courteously but emphatically, rejected his conclusion. Probably if Baly had written four or five years later he would have taken Snow much more seriously, because Snow's conclusive statistical proof that, as we should now say, mortality from cholera and the drinking of polluted water were highly correlated was based upon the epidemic of 1854. Baly, although no statistician himself, had a considerable respect for statisticians and whole-heartedly accepted Farr's demonstration that low altitude and high mortality from cholera were highly correlated. Indeed, it was the basis of his general argument, which was this. The cholera poison is not a vapour or miasma but a solid "something" usually conveyed by air currents. If this "something" reaches a low-lying district, harbouring a poverty-stricken, overcrowded population where filth accumulates, then cholera will arise; low-lying, damp, foggy sites were sites of election. He contrasts the erratic lines of travel and the persistence of cholera with the universality of the great influenza of 1847–8, which no doubt he considered a typical purely miasmatic disease. He was fair-minded; he admitted the possibility—indeed, the probability—that the cholera poison might be introduced by other means, that the disease *might* be contagious. He is, however, almost as reluctant to accept contagion as a *vera causa* as was Henle to admit miasma as a reality.

What must strike a modern reader, and might have struck a contemporary, as Baly's weakest dialectic is in his discussion of how the Asiatic cholera reached Europe and America. He agrees that the cholera could spread against the wind, in the teeth of the Monsoon; he agrees that it followed the line of human intercourse, that it entered at the ports, moved up waterways, and so on. Surely it was easier to suppose that the continuance of cholera in a ship was due to the persistence and multiplication of a *contagium vivum* in the bodies of the patients than to try to exclude contagion from one's argument? That once admitted, conversion to Henle's standpoint would follow. But it is easy to be superior; we know much more about cholera than even Henle and Snow, but no epidemiologist would be bold enough to explain why the epidemic of 1866 was our last.

Baly's section on preventive measures is very short and is no more than a colourless abbreviation of what Southwood Smith and Edwin Chadwick had recommended much more forcibly for the mitigation of *all* epidemic diseases. The devil's advocate may ask whether if the College of Physicians in 1849 *had* officially endorsed what we now accept as the right theory, Snow's theory, many lives would have been saved. I think the answer must be "No."

There is a sentence in Baly's report which was only too true.

> "Quarantine can no longer be adopted as the means of preventing the entrance of Cholera into England; for it is incompatible with the present state of commercial intercourse, and with the well-being of a commercial country."

Perhaps quarantine would not have kept cholera out, but time was to show that something more than fear of epidemics was needed to persuade the electorate to clean up the country.

SATURDAY OCTOBER 8 1949

FAT ABSORPTION

The absorption of the amino-acids and the monosaccharides which are released by the digestion of proteins and carbohydrates in the small intestine is a comparatively simple process, or at least it is generally described as though it were a simple process. But there can be no illusions about the extreme complexity of the processes which are involved in the absorption of fats. In last week's *Journal* (p. 719) we published an authoritative review by Professor H. S. Raper of the experimental evidence which has slowly accumulated during the last 50 years, and the changing interpretations that have been applied to the available information. The "classical theory" which was accepted a generation ago can be briefly summarized. It stated that the food fats undergo complete digestion in the small intestine to glycerol and fatty acids; the latter cannot be absorbed as such because, being insoluble in water, they cannot pass through animal membranes. The fatty acids are converted by the alkalis of the digestive juices in the intestine into water-soluble soaps and absorbed in this form. As neither fatty acids nor soaps are found in the thoracic duct, it was presumed that the absorbed soaps are reconverted in the epithelial cells of the intestine into neutral fat and as such are transported into the lacteals.

This familiar story needed serious amendment when it was demonstrated that the reaction of the intestinal contents was generally too acid to permit of soap formation and that, furthermore, there is not enough base available in the digestive juices to convert all the released fatty acid into soap. The question that needed an answer was how the insoluble and indiffusible fatty acids were converted into the soluble and diffusible form necessary for their passage through the intestinal membranes. Verzar and his colleagues have shown that the bile acids can either combine chemically with the fatty acids or else become associated with them in some looser form as a so-called "complex." The resulting product is soluble and diffusible. This solvent or "hydrotropic" action of the bile acids is enhanced by the lecithin of the bile. Verzar's theory had to meet the objection that there is insufficient bile acid available in the intestine to dissolve all the released fatty acid; but he went on to suggest that after the bile-acid–fatty-acid "complex" enters the intestinal epithelium the bile acid is split off, returns to the intestinal lumen there to pick up a fresh load of fatty acid, and continues to travel back and forth until all the fatty acid is absorbed. The freed fatty acid in the epithelial cells was thought by Verzar to pass through an intermediate phosphatide stage before being re-formed into neutral fat. Phosphatide formation involves the temporary uptake of inorganic phosphate and may be catalysed by the enzyme phosphatase which is present in high concentration in the intestinal mucosa. Some of the evidence supporting the phosphatide hypothesis may be noted: the addition of phosphate or of glycerophosphate to the intestinal contents increases the rate of absorption of fatty acids from a mixture of fatty acids, bile acids, and glycerol; iodoacetic acid and phloridzin, which inhibit phosphatase, depress fatty-acid absorption, and the use of staining methods of doubtful validity purports to show that when these poisons are used fatty acid absorption is blocked because phosphorylation does not occur. It is disappointing to learn that recent studies with radioactive phosphorus have not helped to clarify this problem.

During the last few years Professor A. C. Frazer and his colleagues, of the Birmingham school, have studied the whole question of fat absorption, and the paper on fat metabolism and the sprue syndrome which Professor Frazer read at the Annual Meeting of the B.M.A. in Harrogate last June is published in the opening pages of this issue. The novel features of the hypothesis of the Birmingham school are, first, that fat digestion in the intestine is normally very incomplete; secondly, that neutral fat is absorbed as such in the form of minute emulsified particles; and, thirdly, that the soluble fatty-acid–bile-acid complexes pass directly from the intestine into the portal blood and do not travel via the lacteals. Frazer refers to his theory as the "partition hypothesis," because it supposes that there are two routes for fat absorption—via the lacteals or directly into the blood. Fat particles, so-called chylomicrons, can be detected in the blood under dark-ground illumination as points of light and counted; during starvation they are scanty, but after a fat meal they increase in number. If rats are given well-emulsified olive oil the lacteals appear milky, and the chylomicron count in the systemic blood rises but that in the portal blood remains low. It is concluded that the absorption of neutral fat occurs via the lacteals into the systemic circulation. On the other hand, if a mixture of fatty acids and glycerol is administered the lacteals remain relatively free from fat, but the chylomicron count in the portal blood rises sharply; the fatty acid, on reaching the liver, is retained there and the systemic chylomicron count remains low. It is worth recalling in this connexion the work of Munk, who found, 60 years ago, that only about two-thirds of the absorbed fat can be recovered by "cannulating"

the lymphatics, and concluded that the missing third is absorbed by some other route, possibly directly into the blood stream. If cetyl sulphate is added to neutral fat introduced into the intestine it has two main effects: it produces a very fine emulsion and it inhibits the action of lipase. Though in these circumstances the neutral fat cannot be hydrolysed to fatty acid, it was found by the Birmingham school that fat is absorbed quite rapidly: the lacteals soon become milky, and fat quickly appears in the systemic blood, whence it is deposited in the fat depots but not in the liver.

As Professor Frazer sees it, the most important prerequisite for the direct absorption of neutral fat is its thorough emulsification into particles which are less than 0.5 μ in diameter. The suggested mechanism of emulsification is as follows. Lipase acts on the neutral fat—i.e., the triglyceride (glycerol + three molecules of fatty acid)—in stages, splitting off successively each of the three attached fatty-acid molecules. Removal of one fatty-acid molecule leaves a diglyceride (containing two molecules of fatty acid); removal of the second fatty-acid molecule leaves a monoglyceride (containing one molecule of fatty acid); removal of the third fatty-acid molecule leaves glycerol. Frazer claims that in normal conditions fat digestion is incomplete and that lipolysis comes to a standstill before 30% of the fatty acid contained in the triglyceride is released. The end-products of fat digestion would then be (to use an Irishism) mainly undigested neutral fat together with partially split products (diglyceride and monoglyceride), fatty acids (derived from incompletely and completely split triglyceride), and glycerol. An emulsion of neutral fat of the necessary fine particle size which is stable at the *p*H and in the other conditions found in the intestine can be prepared *in vitro* by mixing neutral fat together with its partially split products (diglyceride and monoglyceride) and the soluble bile-acid–fatty-acid "complexes." This mixture of ingredients is of course exactly the one which is supposed to be present in the small intestine as a result of the preliminary partial digestion undergone by neutral fat in the presence of bile. The newer views reinforce the classical opinion that in normal circumstances both lipase and bile are indispensable for efficient fat absorption, though the way in which these substances act is now described in different terms. Frazer seems willing to accept in a general way Verzar's view that the passage of the emulsified neutral fat particles through the intestinal epithelium may involve transient phosphatide formation. It is likely also that absorption is influenced by local concentrations of electrolytes, by hormones, and even by vitamins. There is a possibility that the adrenal cortex, by regulating electrolyte balance in the body fluids, may be a subsidiary regulating factor. It is now well established that very finely emulsified liquid paraffin in which the particle size is less than 0.5 μ can be absorbed to the extent of 40% by the rat intestine. Fortunately medicinal liquid paraffin, when used in cooking or as a laxative, is not sufficiently finely dispersed to be absorbed to a significant degree in man.

How does all this fresh work aid understanding of the various clinical conditions associated with steatorrhoea? The new theories agree with the old that in the absence of bile or lipase excessive amounts of fat will be lost in the faeces. But the more obscure kinds of steatorrhoea still remain unaccounted for in spite of much careful work, which is well reviewed by Professor Frazer in his paper. In normal individuals over 95% of the ingested fat is absorbed; in the sprue syndrome the percentage falls to 50–80. It is generally agreed that in sprue the percentage of the ingested fat which is absorbed is not dependent on the total amount of fat in the diet. Thus the percentage of fat ingested remains on an average about 60 whether the total fat eaten is 65 or 95 g. daily. The impaired absorption of fat is not due to deficiency of lipase or of bile, nor is it due to inadequately fine emulsification of fat in the intestine. There is then some undetermined fault in the mucosa which hinders the transfer of particulate neutral fat into the lacteals. In other words, it is among the incompletely revealed processes which are concerned with fat absorption that the cause of sprue and related conditions must be sought. The failure in sprue is not limited to absorption of fat; it affects glucose absorption also. Study of Frazer's paper will doubtless suggest many new lines of inquiry.

PROGRESS IN OBSTETRICS

In similar papers read on both sides of the Atlantic last year Haultain[1,2] outlined the progress made in obstetrics over the past twenty years and suggested further possible improvements. His review, which is based on hospital statistics, records a progressive fall in maternal mortality and morbidity which is gratifying to read. Equally noteworthy is the improvement in recent years in the hospital figures for stillbirths and neonatal deaths. Changes for the better in social, economic, and nutritional conditions, the employment of suitably qualified resident obstetricians, advances in medical knowledge and technique, the applications of chemotherapy, and the wide use of blood banks—all played a part in increasing the safety of mother and baby. Haultain rightly emphasizes that in so far as the baby is concerned some of the credit must also be given

to the advent of the paediatrician on to the staff of the maternity hospital. But progress has not been confined to institutional midwifery: the provisional figures for 1948 for the whole country are very impressive, with the maternal mortality rate 1.02 per thousand births, the stillbirth rate 23.1 per thousand births, and the neonatal death rate 19.7 per thousand live births.

At first sight these figures appear to eclipse those which are recorded in recent annual reports from the larger and teaching maternity hospitals, the efficiency of which is usually measured by their vital statistics. The discrepancy, however, is accounted for first by the fact that the Registrar-General's figures for maternal mortality, unlike those from the hospitals, exclude deaths from associated diseases—heart disease, for instance, is a common cause of death in pregnancy. Secondly, as Haultain points out, hospital statistics are greatly affected by the number of women admitted as emergencies, for, excluding those who die as a result of systemic disease, the deaths in hospital occur almost entirely among the cases in which pregnancy or labour has become complicated or has been mismanaged at home. If, however, only booked cases are considered then the hospitals can claim excellent results, even though such patients include many selected for hospital care in anticipation of an abnormal pregnancy or of a difficult confinement. It might be said here that the overall results obtained at different hospitals cannot be compared without making allowances for such factors as the percentage of cases admitted as emergencies and the social and economic complexion of the areas served by the hospitals. The general standard of domiciliary midwifery in any district can usually be appraised by analysing the numbers and types of cases admitted as emergencies to the local hospitals and the condition of those patients at the time of admission.

One method of making further progress would be to reduce the number of emergency admissions, for though in some cases they are unavoidable, in the majority they reflect either on the selection of cases for home confinement or on the conduct of the labour at home. A suggestion which was warmly received at the Twelfth British Congress of Obstetrics and Gynaecology in London last July was the establishment on the American model of a maternal mortality committee in every area to inquire into every maternal death whether at home or in hospital, and to apportion the blame constructively and instructively between patient, relatives, midwife, general practitioner, specialist, and ancillary services. In Chicago, where such a committee exists, Davis and Gready[3] concluded from the analysis of the cases at the Lying-in Hospital that two out of every three deaths could have been avoided. At the British Congress, however, some speakers were fearful that the National Health Service in its present form might hinder progress, especially so far as domiciliary obstetrics is concerned. These critics argued that the Service separates hospital from domiciliary practice, and this at a time when the great benefits resulting from the integration of antenatal, domiciliary, specialist, and hospital services, including the obstetric "flying squad," have been proved. Thus Emblin[4] was able to report that after the co-ordination of these services in his area into a municipal obstetric organization 5,000 consecutive deliveries were supervised with only one maternal death, and that due to leukaemia; at the same time the stillbirth and neonatal death rates were also reduced.

If there is still no integration of the services of those looking after the pregnant woman there is still less integration of opinions on the part obstetricians, general practitioners, and midwives should each play in making what is essentially a normal process still more safe than it is for the mother and the child. The Royal College of Obstetricians and Gynaecologists, in a report issued in 1944, considered that only general practitioners with special experience in midwifery should practise obstetrics, and it was roundly asserted in the *Practitioner* special number on the N.H.S. that "the average midwife is better trained to deal with normal midwifery than is the average general practitioner." If this is indeed the opinion of obstetricians in this country then we suggest that they should seriously look into the adequacy of the teaching they give students in hospital, and into the adequacy of the examinations conducted which enable those who pass them to have their names put on the *Medical Register*. The present attitude of obstetricians to general practitioners is but one aspect of the present tendency to see the general practitioner as someone who sorts out cases for reference to the specialist. We seem indeed to be drifting into the absurd position in which the midwife is looked upon as the specialist in normal and the obstetrician as the specialist in abnormal midwifery. A spirited defence of the general practitioner's place in domiciliary midwifery was published four years ago in this *Journal* by Dr. D. D. Logan and Dr. Eneas K. MacKenzie.[5] "Maternity practice," they wrote, "is the very root of general practice." When the writer in the *Practitioner* attacked what he called "the new type of general practitioner-obstetrician wielding the forceps" had he forgotten the pre-war type of obstetrician who wielded the knife in the practice of caesarean section? In 1935 Dr. J. Bright Banister[6] stated that the incidence of the operation was far too high, basing his observation on a series of 3,486 cases of caesarean section, 1,763 of which were taken from the reports of five large maternity hospitals in Britain during the years 1922–32. If the specialist obstetrician sees mistakes made by the general practitioner he should

recollect that the converse is also true, and the history of caesarean section between the two wars is sufficient illustration of the limitations of the expert. It is most unfortunate that these attacks have been made on the general practitioner, because they can increase neither his confidence in himself nor the confidence of his patients in him. They have created an atmosphere of competition between the general practitioner and the midwife which can lead to no good. No one appreciates the excellent work done by midwives more than does the general practitioner, but surely he can be of no use in an emergency unless he has continuous experience in the conduct of normal midwifery. It is to be regretted that the introduction of the National Health Service has given rise to these wrangles about the competence of general practitioners to do the work for which they were trained. The administrative division of responsibility has not made matters easier. What is essential is to see that the pregnant woman has the best care that can be made available, and in the provision of this the midwife, the general practitioner, and the obstetrician have their essential and complementary parts to play. The family doctor is the one person who fully understands the domestic background and psychological make-up of the woman who is to bear a child. That he should be fully competent in obstetrical technique is first and foremost the responsibility of those who teach him while he is still a student.

CAUDAL ANALGESIA

The visit of Professor R. A. Hingson to Britain this summer has stimulated interest in a new therapeutic concept, the treatment of the various conditions associated with angiospasm—such as eclampsia, reflex anuria, phlegmasia alba dolens, post-traumatic dystrophy, and gravitational ulcers—by continuous caudal analgesia. Elsewhere in this issue we publish the paper which Professor Hingson read on this subject at the Annual Meeting of the British Medical Association at Harrogate.

It had been suspected since 1934 that autonomic vasoconstrictor fibres may be inactivated by concentrations of anaesthetic which have little effect on sensory and none on motor fibres,[1] and this was confirmed in 1946 by Sarnoff and Arrowood.[2] It is thus possible, by choosing the right strength of solution, to single out for attack the vasoconstrictor impulses which are responsible for maintaining a pathologically increased tone in blood vessels. This would be of prognostic use in hypertension even if the effect lasted no longer than a single dose of procaine or amethocaine; but modern developments in the technique of epidural analgesia enable the effect to be maintained without much danger or discomfort for as long as a week or 10 days. The number of vasomotor fibres inactivated can be controlled, and it is possible by the catheter technique to abolish vasoconstrictor impulses arising from a selected band of segments. A temporary and reversible denervation of the kidney and suprarenals can thus be obtained: its completeness—and hence the degree to which the blood pressure is lowered—can be kept constant or varied from hour to hour. Hingson maintains that in certain cases of renal ischaemia the best results can be obtained by alternate dilatation and constriction of the renal vessels, on the analogy of the pavex treatment for ischaemia of a limb. This effect can be produced by alternately carrying the block above and dropping it below the level of the upper thoracic segments.

In a paper[3] published in 1947 Hingson has recorded a number of cases in which the results of treatment were impressive. As he says:

> No one can watch a hypertensive, eclamptic, comatose, convulsant patient in acute heart failure and pulmonary oedema, rescued within 30 minutes by a therapeutic continuous caudal or continuous spinal anaesthetic, which frequently lowers the blood pressure 100 mm. of mercury, and simultaneously relieves headache and blurred vision, raises the skin temperature of the feet 30° F. (16.5° C.), diminishes near fatal pulmonary oedema, slows and steadies the failing heart, increases renal output, and coincidentally abolishes pain, without appreciating that in this mechanism lies one of the most potent weapons the physician possesses to wage against disease and death.

This new therapeutic method has been described[4] as potentially the most important contribution to the treatment of eclampsia in the past decade, for it provides a means of bringing the condition under control without recourse to centrally acting depressant drugs which must increase the strain on an already strained metabolism. Control of eclampsia can usually be maintained for as long as is required, but constant vigilance is imperative.

Continuous autonomic block is not a simple method of treatment; it entails a knowledge of the physiology and the anatomy of the autonomic system and the vagaries of the caudal canal, of the pathology of the angiospastic states, of the pharmacology of local anaesthetic drugs, and a certain amount of manual dexterity. It would seem that the person best fitted to use the method is the well-trained anaesthetist, whose help in these matters is already being sought by his colleagues. However, the control of angiospastic states by this means requires individual attention for long periods, and few practising anaesthetists are able to spend enough time in the wards even to supervise to their satisfaction the post-operative care of their

surgical patients. It may be that a number of therapeutic anaesthetists will eventually be required, familiar with such techniques as continuous epidural, segmental spinal, and lumbar peridural analgesia and with the nerve blocks appropriate to the relief of the many varieties of post-traumatic pain, and experienced in the control of the bronchoconstrictive attacks of asthma and of the vasoconstrictive attacks of eclampsia and allied conditions. To carry out this work, which is time-consuming and cannot be hurried, its practitioners would have to be freed to some extent from the obligation to spend several hours each day in the operating theatre. In the United States and Canada some steps have already been taken to overcome this difficulty, and regular nerve-block clinics, staffed by anaesthetists trained in the hard school of surgical anaesthesia, have been established at many of the larger hospitals.[5]

As a means of relieving the pain of labour and delivery continuous caudal analgesia has been very widely used in North America since its introduction by Hingson, Southworth, and Edwards in 1942, and it has been shown to be a safe and efficient method. Traditional British conservatism probably accounts for the fact that the method has not been taken up to any great extent in this country; other reasons for this may be the comparative stoicism of British mothers, the lower proportion of hospital deliveries, unwillingness to adopt the fashion for forceps which prevails in America, scarcity of anaesthetists possessing both the knowledge and the necessary time, and lack of adequate equipment, which is not yet made in this country. It should be added that other methods of obstetric analgesia are better developed in Britain than anywhere else in the world, but they nearly all entail some degree of general intoxication and transplacental narcosis, and they are thus unsuitable for the handicapped mother or for the premature infant. There is no doubt that continuous caudal analgesia can confer benefits to mother and baby which they should not be denied, and it is to be hoped that obstetricians in this country will not be satisfied until they can obtain it at least for those mothers for whom it is specially indicated.

RADIATION INJURY

The development of atomic energy research has led to a great increase in the number of people exposed to ionizing radiation. Before this development took place the number exposed to risk was comparatively small; many had some knowledge of the biological effects of radiation and nearly all had an appreciation of the possible dangers and necessary precautions. Conditions of work and the measures to be taken for protection were laid down by the British *X*-ray and Radium Protection Committee, an unofficial body formed in 1921, whose recommendations were widely accepted. Methods of handling radioactive materials and of using *x*-ray apparatus became as much matters of care and routine in most radiological departments as are aseptic surgical techniques in operating theatres. Occasional cases of injury have occurred from time to time, however, usually as the result of lack of care or inadequate knowledge. Hultberg[1] has recently published an account of two such cases—one in a surgeon who suffered acute and serious injuries to his hands and in whose blood also some changes were noted after the use on seven occasions of fluoroscopy to control the reduction of fractures; the other in an industrial worker engaged for two years in the fluoroscopical examination of castings, who paid for his disregard of the regulations by the loss of both index fingers.

Work on atomic energy has progressed in secret, and the damage done to human lives in the U.S.A. and Russia during the preparation and testing of atomic bombs is not known. From the information available it appears that serious accidents have been few considering the urgency and vast extent of the efforts made and the large number of work-people who had no understanding of the danger that they could neither see nor feel. Reports of damage have appeared from time to time; the latest, published last month,[2] gives an account of four men injured during tests at Enewetok Atoll, the United States Atomic Energy Commission's proving grounds. Fortunately the men received only a small dose of total body irradiation with gamma rays, but the beta ray doses to their hands were high and the damage serious and permanent. Exposures varied from 40 to 60 minutes. The man least affected had a severe erythema and vesiculation, but the lesions healed with only a little residual reddening at the end of a year. The other three had skin, and in one case tendon, necrosis; prolonged treatment with grafting was required and at the end of a year much disability still remained with the prospect of possible late effects still to come. The details of the tests are secret, but the general account of how this accident occurred is most significant: "This work involved the handling of radioactive materials which emitted large amounts of beta and gamma radiation. A deviation in the prescribed procedure undertaken to expedite the operation resulted in the handling of these radioactive substances directly with rubber-gloved and sometimes with bare hands rather than with the remote handling devices that had been provided." "Deviations in prescribed procedures" are generally at the bottom of such accidents, which are commonly due to lack of knowledge. Those whose duty it is to lay down regulations have to remember that they are unlikely to be carried out unless the people concerned possess some understanding of the reasons which make them necessary, and those in charge of work-people who may be exposed to radiation have to develop a sense of personal responsibility for their safety and be prepared to lose their reputation for professional competence should accidents occur.

Arrangements for protection against the dangerous effects of radiation have been admirably conducted in this

[1] *Acta radiol. Stockh.*, 1949, 32, 17.
[2] Knowlton, N. P., *et al.*, *J. Amer. med. Ass.*, 1949, 141, 239.

country in the past. International recommendations, based largely on the British proposals, were adopted in Stockholm in 1928 by the Second International Congress of Radiology at the instance of the British committee. Much arduous and valuable work has recently been done by the protection subcommittee of the Medical Research Council's committee on the medical and biological applications of nuclear energy and by its tolerance doses panel. Under the Radioactive Substances Act the Government has taken wide powers of control over the manufacture, supply, and disposal of radioactive substances. It has the power to impose safety regulations for occupations in which radioactive substances and irradiating apparatus are used. It is to be hoped that as more people are employed in occupations in which irradiation is a hazard tragic "deviations from the prescribed procedure" will be avoided. People with no real knowledge of the dangers do not regard official regulations in the same way as those who, understanding the dangers, accept recommendations made for their protection by their own professional bodies.

MYOIDEMA

The phenomenon of myoidema has aroused interest from time to time since it was first described by Robert Graves and William Stokes[1] in 1830. Its distinction from myotatic irritability has not always been appreciated, though most of the earlier writers were emphatic on this point. For instance, Lawson Tait,[2] who suggested the term "myoidema," insisted that a "nodule or intumescence" of muscle at the point percussed was the essential feature of the sign; he frequently observed the sulcus or linear contraction of myotatic irritability in the healthy. Although once believed to indicate pulmonary tuberculosis, and even thought to have a value in determining which side was diseased, myoidema is now usually stated to occur in most diseases associated with wasting. Denny-Brown and Pennybacker,[3] in their detailed study of fibrillation and fasciculation in voluntary muscle, observed two patients with malignant disease who presented this sign. They concluded that myoidema was a response of the whole muscle fibre to intense mechanical stimulation. It appeared to them to be an exaggeration of a normal phenomenon and unrelated to the fine fibrillation of denervated voluntary muscle or to the fasciculation so characteristic of motor neurone disease.

The cause of this increase in muscular excitability has remained a matter for hypothesis, although Koumans[4] and Seto[5] believed that malnutrition and vitamin deficiency were important factors. In this number of the *Journal* Drs. G. F. Taylor and P. W. Chhuttani bring forward further evidence supporting this suggestion. They noted the frequency of myoidema in Indian troops in the Middle East and Iraq, and in a detailed survey found that it was higher in Indians in hospital than in those on duty; higher in vegetarians than in meat-eaters; and higher in Iraq than in Syria and Lebanon, where conditions were less arduous and, perhaps, the diet better. Myoidema was less frequent in British troops than in all other groups examined. The authors were able to relate these variations in incidence with the frequency of vitamin deficiency as indicated by angular stomatitis, glossitis, cheilosis, and Bitot's spots. Severe myoidema was noted in each of 82 patients with peripheral neuritis, and its intensity diminished *pari passu* with the improvement which followed treatment with thiamin. In addition, many men with vague myalgia and muscular cramps presented intense myoidema; in these also the symptoms disappeared after the administration of thiamin. Taylor and Chhuttani conclude that in the patients they observed myoidema was related to the nutritional state and was probably a sign of thiamin deficiency. This conclusion may help to rescue myoidema from the limbo reserved for physical signs of undetermined significance and doubtful importance.

TRICHOSTRONGYLUS AND STRONGYLOIDES

Infestation of herbivorous mammals with various species of the nematode *Trichostrongylus* is common throughout the world, far more so than human infestations, which formerly were regarded as accidental, the result of proximity to infected domestic animals. But records of *Trichostrongylus* as a human parasite have been appearing with increasing frequency, from India, Russia, Africa, N. America, and especially from the Far East, where *T. orientalis* is stated to be not uncommon as an infection in agricultural workers. The account in last week's *Journal* (p. 737), of a helminth survey in Abadan by Dr. I. S. Stewart serves to emphasize the probability that *Trichostrongylus* may have a much wider range in the human host and be more prevalent than was suspected, for in routine faecal examinations its eggs may easily be overlooked because of their close resemblance to those of hookworm. Although the degree of the infection in the Abadan survey was light, the number of positive results recorded (70%) is surprisingly high, and suggests not only that the circumstances are favourable for oral ingestion of the infective larvae but that the species appears readily adapted to the human host. The identity of this species is not yet known, but failing its determination by the recovery of adult worms at necropsy some information might be obtained by identifying the species harboured by the local sheep, which are evidently the original source of the human infection.

In quite a different category is *Strongyloides (S. stercoralis)*, a well-established human helminth which is harboured by some 35 million people in tropical and subtropical countries; its distribution is similar to that of hookworm. Unlike *Trichostrongylus*—the similar sounding name is of little significance—whose life-cycle is direct and simple, *Strongyloides* undergoes a very complex and varied development. This is exemplified particularly in its free-living or exogenous phase, which culminates in infective skin-penetrating larvae comparable with those of hookworm or in a free-living sexual generation which in turn produces infective larvae. Research in recent years has shown that the parasitic phase in the human body is also highly complex. Contrary to the belief that no

helminth can multiply inside the body of its host but must pass its offspring to the exterior, the larvae of *Strongyloides* are apparently capable of substituting an internal migration for the usual external migration. They pass from the small intestine, where the parasitic females reside, through the gut wall to the circulatory system, thence to the lungs and back to the intestine, where they reach maturity. Pulmonary changes, of which Dr. F. L. Corrigan has recently recorded an interesting example in this *Journal* (October 1, p. 738), are associated with this phase, in which, it is assumed, repeated invasion of the tissues by the migrating larvae reduces the local tissue resistance.

PROTECTING THE CONSUMER

The Government decided in November, 1943, to make the Minister of Food responsible for exercising the powers previously given by Parliament to the Minister of Health, under the Food and Drugs Act, to make regulations dealing with the composition and labelling of food. The opportunity was taken to modify statute law. The Defence (Sale of Food) Regulations altered the definition of food to include any substance used as a food for human consumption even though it is also capable of being used as a medicine, and, in addition, made it an offence to describe falsely or otherwise to mislead the public on the nutritional or dietetic value of a food. This and subsequent legislation was of such a detailed nature that the Ministry of Food undertook to advise the trade on labelling and advertising. In this way it was hoped to secure compliance with the law by the co-operation of traders. Accordingly the administration of these regulations has been based on the assumption that more can be done by persuasion to secure the elimination of misleading descriptions and claims than would be possible by the processes of the law. The achievements of the Ministry in this field of consumer protection are impressive and have brought about many changes in the descriptions of, and the claims made for, pre-packed foods and, indeed, in the outlook of manufacturers. An interesting account of four years' work in this field has recently been published.[1]

Some of the quite unjustifiable claims which came under scrutiny are quoted. A breakfast cereal food claimed "phosphates for the teeth and bones, and iron for the blood"; the label on a packet of dried herbs claimed that it provided "vitamins A, B, and C"; and there was a food consisting mainly of flour which quickly restored to health "infants in the last stages of emaciation." All of these claims and many more similar ones have been abandoned or greatly modified. There was obviously plenty of scope for reform, and the Ministry, in the exercise of a duty to the consumer about which too little is known, has based its actions and advice on certain general principles. It has been accepted that, when a name or description of a product incorporates the name of a food, that food must ordinarily be present in a significant quantity; that if the description of a food includes the names of two or more ingredients—for example, "malt extract and cod-liver oil"—the ingredient present in greatest quantity should be named first; and that qualifying adjectives which indicate the true nature of a food should be given the same emphasis as the rest of the description. On nutritional or dietetic claims difficulties have arisen not so much with the false claims for which there is no scientific foundation as with the claim which implies that a food has a dietetic or nutritional value when in fact that value is insignificant. The Ministry has taken the obviously sound view that if it is claimed that a food is nourishing it ought to contribute a significant amount of nourishment; if a food is said to be "body building" then it should provide a material amount of protein, and so on. In assessing the justification for such claims account is taken of the amount of the food ordinarily consumed in a day by the average individual. Difficulties of this kind led the Ministry to seek the advice of the Medical Research Council about vitamins and minerals in the diet, and resulted in the adoption of a code of practice which exemplifies the twin principles that nutritional claims must be justified by the presence of a significant quantity of the substance and with regard to the amount likely to be consumed by the average person.

The Food Standards Committee set up to advise the Minister has been responsible for the introduction of standards of composition for certain foods. The future programme of this committee is heavy, and many of the foods which in due course will come under review are meanwhile the subject of codes of practice. These codes, which are set out in detail in the report, represent agreement between the Ministry and informed trade opinion on the descriptions and standards appropriate for particular classes of food. They have not the force of law, but they are generally accepted by traders and have done much to protect the consumer from being misled.

DISTINCTION AWARDS

Consultants and specialists considered to be eligible for distinction awards are being asked by the Awards Committee to fill in a form and give details of their qualifications and experience. In this form the candidate is invited to give details of degrees and other qualifications under the heading of "university and/or medical school education," of academic distinctions such as prizes and scholarships, of clinical training and experience, of present and past appointments, and of teaching experience. He is also asked to give details of research and publications and of war service. Space is also left on the form for "any other information and remarks." In referring last week to the suggestion of a points system of assessing distinction we did not mean to imply that the Awards Committee was attempting to assess candidates without such detailed information as is now being sought.

Dr. Geoffrey Marshall, O.B.E., F.R.C.P., will deliver the Harveian Oration before the Royal College of Physicians of London (Pall Mall East, S.W.) on Tuesday, October 18, at 3 p.m. His subject is "Individuality in Medicine."

ON BECOMING A GOOD DOCTOR

BY

SIR HUGH CAIRNS, K.B.E., F.R.C.S.

We print below a slightly shortened version of the inaugural address at King's College Hospital on September 30.

Our medical world is in a state of rapid change. On the one hand we have the National Health Service, which is faced with the stupendous task of providing not only doctors and nurses but also sufficient hospital beds and good equipment to meet the needs of the nation's sick. On the other hand we have the changes wrought by medical research and discoveries in the basic sciences, and these changes have become more numerous and more important in the last 30 years than they used to be. Think only of the effect of the discovery of insulin and penicillin and of the modern treatment of anaemia. That is not all, for looming close ahead are substances which will be effective in treatment of the various types of rheumatism and cancer. You might suppose from this conjunction of changes, and from what has been said about social medicine and health centres, that the majority of the doctors of the future will spend their time in preventing disease, in keeping people well. I do not think that things will turn out that way. So far from reducing the hospital population these life-saving discoveries seem to increase the need for yet more hospital beds. Beds are required often for long periods to treat patients who would have died but for the new remedies. And more often than not these patients survive to get ill again on some future occasion. Undoubtedly there is a big field to be developed in prevention of disease and ill-health, but the fact remains that for most of us the main task of the future will be, as it has been in the past, the care of sick people. Our main objective is to become good doctors.

A Good Doctor

How does one become a good doctor? When one doctor says of another, "He is a good doctor," there is a particular meaning. You will hear the expression used not only about some general practitioners but also about some specialists. As I understand it a good doctor is one who is shrewd in diagnosis and wise in treatment; but more than that, he is a person who never spares himself in the interests of his patients; and in addition he is a man who studies the patient not only as a case but also as an individual.

Diagnosis and treatment are of course the basis of our work with patients. We learn these subjects day in and day out as we walk the hospitals, and we have to pass examinations in them. I do not propose to discuss them except to emphasize that after graduation none of us is infallible; if we accept this fact and are prepared to go on learning, our mistakes will tend to become less frequent and less serious.

How does one learn to devote oneself unsparingly to one's patients? You cannot get this from books or from formal clinical instruction. It is something which is passed on from one generation of doctors to the next, and the easiest way to acquire it is to work with a doctor who already has it in his blood. Lister, for example, was a good doctor: he used to visit his patients in King's every day, including Sundays, and his eminence and his preoccupation with research did not prevent him from showing great understanding and consideration of their feelings.

Your patients need from you more than diagnostic and therapeutic efficiency. They do not come to you to be cured; they come to be relieved of their pains and other symptoms and to be comforted. Given the choice, they would usually prefer a kind doctor to an efficient one. Never forget that the patient and his relations are usually frightened and anxious—upset in their normal life to such an extent that they are prepared to call you into their lives and to tell you the most intimate facts about themselves, though you may be unknown to them except as a member of an honourable profession. In their anxiety, especially when things are not going well for them, they may on rare occasions be rude to you and offend your dignity. This may be hard to bear, especially in the early days of one's medical life before one has lost one's self-consciousness at the bedside and has become wholly familiar with clinical technique. Under such trials you must humble yourself and continue to treat your patient with consideration and kindness, never forgetting for one moment that he is an anxious and overwrought individual, and that in seeking your advice he has paid you the compliment of admitting you to his life and confidence.

A Sense of Urgency

Emergencies teach you how to devote yourself unsparingly to your patients and give that sense of urgency which all good doctors have. To have a share in saving the life of a patient who is dying from haemorrhage, peritonitis, respiratory obstruction, or meningitis is an essential part of the doctor's education. You learn then to observe quickly, to pick out the essential points of the illness, to apply first principles of therapy promptly, and to think clearly even when you are wracked with anxiety about the patient's welfare and your own responsibility for it. This anxiety which an emergency arouses in you is an inevitable and normal reaction—enough to numb all thought but for your training. Don't run away from it, or seek to hide it beneath swagger and pomposity. Instead, familiarize yourself with it by staying with the patient at his bedside, by helping to nurse him, and by making accurate record of the events as they occur. Student nurses seem to assume their responsibilities in such cases more easily than do medical students; it is the difference between the practical and the theoretical approach to the problem of saving human life.

The good doctor, whether general practitioner or specialist, is also a man who studies the patient's personality as well as his disease. In the past this was done by the light of nature: the good doctor started by being interested in his patients as individuals, and eventually his experience taught him to size up quickly most types of mankind and to know the reaction of each type to disease. This was instinctive unformulated knowledge. But now the position has changed, thanks largely to the medical work during the recent war, when we were fighting for our lives and it was realized that the adjustment of each individual to the conditions of war, and his capacity to work and fight, depended as much upon his personality as on his physique.

The manifestations of an illness are much coloured by the personality of the patient. What you are studying at the bedside is not disease but disease in a patient. When you are asked to stitch up a cut finger it may not seem to matter very much what type of personality the patient has; though it is rather fun to try to find out without taking too much time about it. But if the patient has broken his leg, or has to undergo any prolonged illness, his subsequent successful return to his work, and his happiness at home, will largely depend on what type of man he is and the particular measures which are taken to deal with his reactions to illness. Of the people who are suddenly removed from their normal life by breaking a leg, some may be perfectly philosophical and sensible, with assured jobs to which they promptly return when the leg is mended; but others may be so constituted or circumstanced that they are consumed by genuine or imagined worries which will produce strange symptoms, symptoms which are not in the textbooks. And if not treated these symptoms will interfere with the patient's return to normal life.

The study of personality of patients is not a matter for the psychiatrists: it can be formulated on systematic common-sense lines, and it is something which all doctors can do themselves. And it can be learned by the medical student. What it amounts to in essence is that in addition to studying the patient's disease you find out about his life and work and family background. If you are prepared to give the time to listening to what he has to tell you of himself you will be richly rewarded not only by rapidly acquiring a knowledge of human nature but also by increasing your effectiveness in treatment. And the patient will have much more confidence in you than if you merely regard him as a case.

Science and Research

So far I have talked about the art of medicine, and now I must say something about the science and its relations with the other sciences. It must already be clear to you that progress in clinical medicine is largely dependent on advances in the basic and biological sciences. In my student days when we passed our examinations in physics and chemistry, and even in the pre-clinical subjects, we often said to ourselves: "Thank goodness that's over and done with." This was a short-sighted policy, and with each new application of science to medicine—such subjects as electronics, modern statistical methods, radio-active isotopes, and the application of plastics in surgery and dentistry—I find myself regretting my lack of basic scientific knowledge.

No one can hope to keep up with more than a fraction of the work which is going on, but, such is the pace and power of scientific progress, it is essential for your competence and your intellectual comfort as doctors that you should maintain a general interest in scientific matters. This sounds a tall order, but it is surprising how much you can glean from the popular scientific journals and from talking to your scientific friends. Never forget that there is so very much in medical science which is still unknown. Beyond the established knowledge that is set out in your textbooks there are many things which will be discovered in your lifetime, often with profound influence on your medical practice.

What part can the clinician himself play in research? There is scarcely a disease in which a thorough and sustained clinical investigation will not add new facts, and occasionally discoveries of outstanding importance can be made by clinicians who keep good records and are alert to observe the unusual. A recent example is the discovery by Gregg, an Australian ophthalmologist, that German measles in the early months of pregnancy may seriously damage the organs of sight or hearing of the foetus. The application of scientific discoveries in the clinical field—for example, the application of new remedies—also requires careful clinical research; and the whole clinical field is full of problems which can be worked out by a combined attack in the wards and laboratories.

Lister's Inaugural Address

One must be prepared to approach one's clinical problems on the broadest possible basis. In the last 50 years, with the growth of specialization there has been a dangerous narrowing of medical activities. I can best illustrate this trend by reminding you that when Lister was appointed as professor of surgery to this hospital his inaugural lecture was mainly on the fermentation of milk. What would people think to-day if a professor of surgery gave a lecture about milk? They would say that he was neglecting surgery and encroaching on the field of the bacteriologist or hygienist. But to Lister it was a perfectly natural thing to do. Bacteriology was a young subject to which surgeons as well as others were making important contributions. Lister owed his discovery of antiseptics to two things: first, to his thorough and persistent study, at the bedside and in the laboratory, of the healing of wounds; and, secondly, to his broad approach to the problem. When his colleague Thomas Anderson, the professor of chemistry at Glasgow, said to him one day: "By the way, have you read the papers of a French chemist Pasteur on fermentation?" Lister read these papers, and with his prepared mind at once realized that it might be the living germs described by Pasteur and not the oxygen of the air which caused wounds to putrefy. And so began his use of carbolic acid. In the lecture on milk Lister was proving again for the sceptics that there was no such thing as spontaneous generation and that the bacteria in the wound came in from the air. This principle was essential for his antiseptic system. Also in this work with the *Bacterium lactis* Lister developed a successful technique for obtaining a pure culture of a bacterium; this was the first time it had been done. Thus Lister approached his problem not only as a practising surgeon but also as a pathologist, as a bacteriologist, and as an experimenter; and, as I have advised you to do, he cultivated his scientific friends. The chemist Thomas Anderson, I have been told, not only drew Lister's attention to Pasteur's papers but also told him about carbolic acid as a possible disinfectant.

One Investigation

You may be thinking that I have been holding out to you ideals which are impossible of attainment. I have been urging you to become good doctors, to keep up with scientific progress, and to undertake research. How can one man do all these things? The answer is that no one can excel in all fields. You will evolve in different ways. Most of you should become good doctors, some will take readily to research, while others, and they will include many good doctors, will have no aptitude for it. But I do think that nearly every young doctor should try his hand at one investigation—should try to carry knowledge of some disease or symptom or function, or the effect of some form of treatment, a stage further than it has been carried before. Otherwise he will not find out what he is good for, nor will he appreciate the difficulties and labours involved in discovering new things.

I have not said anything about material objectives—careers, salaries, and so on. In medicine direct pursuit of these not unimportant aspects of life is apt to prove disappointing, and the greatest personal success is usually incidental to a life spent in service to patients or in research. That is one of the dignities of our profession. We are still, I am thankful to say, a guild, and in the course of your careers you will receive much help from your seniors which you cannot hope to repay, except by passing it on to the next generation. It remains for me only to wish you all a fruitful and happy life, and to express the hope that you will successfully maintain the fame and tradition of this great hospital.

CO-ORDINATION OF TUBERCULOSIS SCHEMES

ADDRESS BY SIR ANDREW DAVIDSON*

Sir Andrew Davidson began by saying that notwithstanding the limitations of health statistics, there was enough evidence to support the view that Scotland's health was being well maintained and, in many directions, further improved. Such a sensitive index of social health, for example, as infantile mortality was in 1948 the lowest ever recorded; and that record should be broken by the current year's figure. Yet while the prevailing trends gave reason for optimism there was no room for complacency, and there were many problems still to be solved. The most immediate one was the control of tuberculosis, which remained the black spot on Scotland's health record.

During the last war the death rate from tuberculosis rose quite steeply in Scotland; but, while in most countries the rate began to decline soon after the war was over, in Scotland it remained high, especially in the West Central area of the country and to a less extent in the Lothians and East Central area. The reason—or more likely the combination of reasons—had not been elucidated. In regard to respiratory tuberculosis, the overall Scottish position could be expressed in round numbers: there were about 30,000 names on the tuberculosis registers; 8,000 new notifications during the year 1948, when there were 3,400 deaths; some 2,500 patients awaiting admission to hospital; and nearly 5,500 beds available for treatment and isolation, of which nearly 600 were empty and unstaffed. This was the background against which schemes for controlling tuberculosis should be considered.

Development of Tuberculosis Services

Measures to control the disease did not really begin until Sir Robert Philip in 1887 established in Edinburgh the first tuberculosis dispensary in the world. Other dispensaries followed, and in 1912 pulmonary tuberculosis was made

*This address by the Chief Medical Officer of the Department of Health for Scotland was given at a refresher course on tuberculosis under the auspices of the National Association for the Prevention of Tuberculosis in Edinburgh on September 20.

notifiable in Scotland. In 1914 all forms of tuberculosis were made notifiable, and thereafter the full local authority anti-tuberculosis service gradually developed. The anti-tuberculosis service before 1948 was operated by each major local authority, the scheme being under the administrative charge of the medical officer of health. As time passed, the actual clinical work in the hospitals, and in many cases in the clinics, tended under the larger authorities to be carried out by men with special experience who might well be regarded as of consultant or specialist status. In less populous areas, however, the medical officer of health might have only a few beds at his disposal. The clinical work was carried out by himself or by an assistant, and the health visitors were too few for any of them to specialize in tuberculosis work. There was in fact every possible gradation between a highly specialized service in some of the large cities and counties and an extemporized patchwork service in some of the smaller authorities.

In the early days it was assumed, rightly or wrongly, that diagnosis and treatment, which constituted the clinical part of the work, were incidental and were possibly not quite as important as were the more preventive functions. Diagnosis, however, improved when the *x*-ray apparatus became more generally available, and special measures of treatment gradually developed also. Hence, as the years passed, the task of diagnosis tended to grow in importance; and treatment tended also to enlarge in scope.

The value of the services was best shown by the steady drop in the mortality of respiratory and non-respiratory tuberculosis. For instance, in the years 1931 to 1939 the death rate from respiratory tuberculosis fell by 12% and the death rate for non-respiratory tuberculosis by 35%. Not all of these decreases can, of course, be attributed to the anti-tuberculosis service. Improved housing, improvement of milk supplies, and the general process of social amelioration all played their part.

The purpose of the National Health Service Act in dealing with tuberculosis was not to condemn the former anti-tuberculosis service as inefficient, but rather to take the service which had showed all shades of efficiency and which had on the whole done good work and to try to improve it and strengthen it still further. The National Health Service Act unified the hospital service, and the special hospitals which dealt with tuberculosis and infectious diseases were swept into the general pool. In Scotland hospitals of all types—teaching and non-teaching alike—came within the administrative purview of the five regional hospital boards.

The environmental and preventive side of the subject was dealt with in Section 27 of the Scottish Act. The control of tuberculosis as opposed to the treatment of it remained primarily the work of the local authority. The local authority was enabled to make arrangements for the prevention of illness, for the care of persons suffering from illness, and for the aftercare of such persons, and these arrangements were subject to approval by the Secretary of State. The Secretary of State had directed that arrangements should be made by every local health authority (i.e., by the counties and by the large burghs) for the purpose of preventing tuberculosis and for the care and aftercare of persons suffering from that disease. The duties which were formerly discharged by the local authority and their medical officers of health were therefore squarely laid once more upon the same shoulders, with the exception that clinical care and hospital treatment had now been transferred to the regional hospital boards. Some of the methods by which the local authorities could discharge their obligations were as follows:

(*a*) The provision of adequate housing for tuberculous families, of garden shelters where appropriate, of night sanatoria as a means of preventing the dissemination of the disease, and the boarding out of children who were living in contact with cases.

(*b*) Provision of advice regarding segregation in the home. Provision of facilities to assist in such segregation, e.g., beds and bedding. Provision of nursing requisites, clothing, and extra nourishment.

(*c*) Provision either in co-operation with the Ministry of Labour or by the local authority themselves of suitable workshops for employment of the tuberculous.

(*d*) Provision of health visitors for services in the home and in the tuberculosis clinic.

The primary responsibility for the patient at home, and particularly for early diagnosis, must rest with the general practitioner. But the general practitioner was not working in isolation: he had all the resources of the local authority to support him, and to assist with diagnosis and treatment the regional hospital boards had been charged with the duty of providing domiciliary consultations. Regional hospital boards had the responsibility for providing dispensary and hospital services incorporating up-to-date methods of diagnosis and facilities for modern treatment. Obviously the treatment side under the regional hospital board required a double integration. It must be closely integrated with the general medical services of the area, and, perhaps even more important, with the epidemiological, social, and environmental aspects of the work. Therefore, regional hospital boards had been advised that dual appointments might be of permanent advantage in certain circumstances; that the tuberculosis officer, or chest consultant, as he was now termed, who took charge of treatment might also act under the medical officer of health in connexion with the preventive work. Whether such dual appointments were made or not, regional hospital boards must have regard to the continuing responsibility of the local authorities for epidemiological measures in their area.

Intention of the New Legislation

In the recent legislation, Sir Andrew Davidson continued, it was thought necessary to unify the hospital services under a single control in order that these services could operate generally with the maximum efficiency. The best possible use should be made of all hospital accommodation irrespective of the functions for which it was originally provided, and irrespective of the circumstances of a patient's residence. Also it was thought desirable to form a clinical tuberculosis service in which avenues of promotion would be open to those working in peripheral areas and to bring to an end many of the so-called blind-alley clinical occupations. Except in some of the larger authorities the tuberculosis officer of the past either tended to occupy one of these blind-alley positions or else accepted his post in tuberculosis merely as a step on the ladder towards an administrative post. Such a situation was not beneficial either to the tuberculosis service or for that matter to the public health service as a whole.

But no reform came without creating its own difficulties. The major difficulty which faced the tuberculosis service at the present time was ensuring full and adequate co-operation between the health officers and the hospital service. A balance still had to be kept between treatment in hospital and isolation of infection. The hospital service was to discharge both these functions. In the main the anti-tuberculosis service functioned at present much as it did in the past, although now the tuberculosis officer was the servant of the regional hospital board. In some cases he had charge of beds which he did not have before, but in all cases he must assist in carrying out the statutory preventive duties laid upon the local authorities. The net result should be that the tuberculosis officer had enhanced status. He had more fully at his disposal the resources of the hospital service for diagnosis and treatment, and he still remained the head of the tuberculosis service (under the administrative control of the M.O.H.) with the same resources as before of a clinic, clerical assistants, and health visitors.

The medical officer of health was in a position to frame new developments for his area and to ensure their application; his duties would include ascertainment. Notifications came to him, and with the tuberculosis officer he could study these notifications from the epidemiological point of view. He could ensure through his health visitor staff that the patient was suitably directed into the scheme for treatment. He could supply domiciliary aid in the way of nursing care and domestic assistance. He could give priority to the rehousing of suitable families. He could insist that his policy on examination of contacts and their further management was observed. He could enlist the service of mass radiography and ensure that it was directed advantageously towards the control of the disease. He could initiate surveys—for example, tuberculin surveys of groups of his population—adopt preventive measures, and in the near future might be able to start work with B.C.G.

It would be a mistake to attribute all the difficulties and frustration which existed at the present moment to the Health Service Act. Scarcity of hospital staff and beds, for example, were not unknown before 1948, and were probably the principal source of anxiety to all workers in the field of tuberculosis. If the old system had remained there was no reason to imagine that more hospital staff or more hospital beds would have been available. Indeed the situation in respect of hospital beds had been improved already by the new Act, and if there were no difficulty in staffing these beds a considerable addition could be made already to the number of beds available for tuberculosis. Many of the complaints about the working of the scheme would disappear if an adequate number of staffed hospital beds became available.

For achieving results in the field of tuberculosis co-operation was the definitive word and implied genuine co-operation between clinician and health officer, between hospital service and local authority, between hospital service and general practitioner, and between local authority and general practitioner. It meant an active partnership where each member of the team saw not only his own facet but something of the whole picture. Some might be tempted to have a certain cynical regard for the word "co-operation"; but the administrative structure had been laid down and must be assumed to have some permanence, and the various services, hospitals, local authorities, and general practitioners must work together. In all this, the health officer and the health visitor had a major part to play.

LOCAL HEALTH AUTHORITIES AND TUBERCULOSIS

PREVENTION AND CONTROL

A joint meeting of the Society of Medical Officers of Health and of the National Association for the Prevention of Tuberculosis held in the Great Hall of B.M.A. House on September 15 was attended by some 130 delegates.

Professor R. H. PARRY, president of the society, was in the chair and was supported by Sir ROBERT YOUNG. He said this joint meeting gave them an opportunity to exchange views on the arrangements made by local health authorities for prevention, care, and aftercare under Section 28 of the National Health Service Act, 1946. He said that they were now just beginning to find their feet, and it was an appropriate time for reviewing the position in regard to the biggest public health problem of the day.

Sir ALLEN DALEY said that real prevention of tuberculosis was founded on conditions of life—housing, general nutrition, and hygiene. Some years ago he had conducted an investigation to see whether there was an inverse relation between the decline in tuberculosis and the rate of expenditure on hospital and medical services. No such relation had been discovered. He thought it important therefore that the public health service should concentrate on the basic conditions which affected the disease and keep a close watch especially on the general nutritional state of the people. The second aim of prevention was the isolation and removal of the patient. He did not think that the legal power under the National Assistance Act, 1948, for compulsory removal to an institution was of much practical value in cases of tuberculosis. The chronic ambulant infectious case who was homeless presented a problem. Local health authorities should consider the provision of special hostels, although these would be difficult places to manage and control. Alternatively, people living in houses with surplus accommodation might be persuaded to give rooms to such ambulant cases. Children in contact with open tuberculosis should be boarded out on the Grancher system. Some 600 London children were being cared for on this ground, mainly in residential nurseries and schools.

Sir Allen considered that mass radiography was best placed under the control of regional hospital boards provided that the local health authority advised on its best use. He believed that there should be arrangements for the *x*-ray examination of all persons in regular contact with groups of children; there were 30,000 such people in London. Another essential in prevention was good health-visiting in association with the chest physician.

Dr. G. W. H. TOWNSEND (Buckinghamshire) discussed problems peculiar to counties and rural areas. In his experience the district councils had made little use of their powers under the Tuberculosis Regulations. Would the local health authorities do any better now that they had lost their functions in regard to treatment and retained only those of Section 28? He thought that welfare work confined to tuberculosis was time-consuming and should be combined with that for other conditions. Good co-operation between health visitors and welfare workers was essential. The tuberculosis service might also take a leaf from the maternity and child welfare book. Mothers at welfare centres waiting to see the doctor were learning all the time by lecture, film, or leaflet. At the tuberculosis dispensary waiting was just waiting, and here there was an opportunity for health education on welfare centre lines.

Dr. STUART LAIDLAW (Glasgow) said that more evidence was wanted on the relation of overcrowding and tuberculosis. In Glasgow they had found that the contact rate was twice as bad in 2–3-room houses as in 3–4-room houses. He disagreed with the attachment of the chest physician to the regional hospital board. The effect had been concentration on the curative and clinical aspects, and interest in the domiciliary side had waned. There was in Glasgow a waiting-list for sanatorium beds of 16,000, but no chance of admission unless the case was of special clinical interest. The M.O.H. had no power to enforce admission, so a day-to-day battle was in progress to get cases away from dangerous home conditions. Referring to Sir Allen Daley's point about hostel accommodation for ambulant cases, Dr. Laidlaw described how an empty ward in a tuberculosis hospital had been reopened as a hostel for 60 discharged patients who shared the catering and domestic work.

Dr. W. ALCOCK (Burton-on-Trent) speculated whether the decline in tuberculosis mortality was due to environmental improvements of the past 75 years or to a variation in virulence such as one saw in other infectious diseases. It was an inevitable conclusion that environmental and social betterment was fully responsible in this instance. He thought, however, that the factors of resistance, susceptibility, and acquirement of immunity still required much investigation, but suggested that when employment was high, housing good, and leisure time wisely spent tuberculosis would further decline.

Dr. K. NEVILLE IRVINE (Henley-on-Thames) said he would confine his remarks to three questions. (1) Should B.C.G. be given to selected cases or *en masse*? The Ministry of Health had decided on selection.

(2) Why was segregation required for six weeks before and after vaccination? It was wise to observe this rule in the interests of the prestige of this new procedure. If pre-segregation was impossible, they could vaccinate in the pre-allergic state. Likewise, if the Mantoux test six weeks after vaccination was not positive, there should be another test at 10 weeks before re-vaccination; some people were slower than others in conversion. When re-vaccinating after 10 weeks he advised a double dose. Failure to segregate after the first vaccination did no harm, but some cases might contract the disease before immunity was established, thus damaging the reputation of this form of protection.

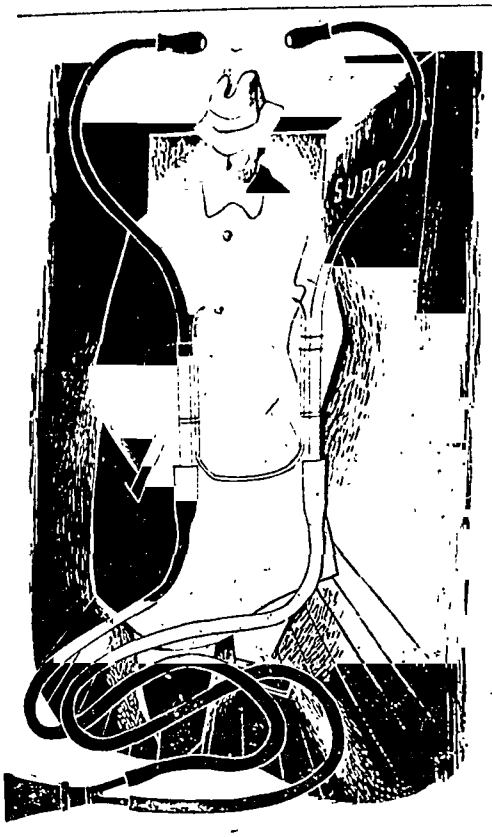
(3) Was intracutaneous injection preferable to multiple puncture? This had been settled by the Ministry's decision to use the Copenhagen serum, which was specially prepared for intracutaneous injection. The dose should be doubled for newborn infants. Patients should be warned about the papule which might appear after two or three weeks and sometimes broke down to an oozing ulcer. Ultra-violet light cleared up such persistent ulcers with dramatic speed. Speaking of the groups to be selected, Dr. Irvine suggested that Mantoux-negative diabetics should be included as should Mantoux-negative cases in tuberculous families, especially those in contact with streptomycin-resistant cases.

There followed a general discussion in which a number of speakers took part.

ORAL . . . *tablets of Methyltestosterone B.P. of 5 - 10 - 25 or 50 mg.*

INJECTION . . . *ampoules Testosterone Propionate B.P. 5 - 10 - 25 or 50 mg. in 1 cc. & 100 mg. in 2 cc.*

IMPLANTATION . . . *fused pellets of 100 mg. Testosterone in sealed glass tubes.*



OINTMENT . . . *Testosterone Propionate B.P. 2 gm. tubes 25 mg. per gm. 25 gm. tubes 2 mg. per gm.*

SUPPOSITORIES . . . *Testosterone 15 mg. in each*

"the patient who won't fit in...."

The mentally depressed patient who will neither "fit in" with his surroundings nor co-operate in treatment presents a stubborn and increasingly widespread problem in these difficult days. In such a case, a drug is called for that will improve the patient's mental outlook and overcome his inertia. The answer, both in sickness and in convalescence, is provided by the remarkable stimulant effect of

PHYSIOLOGICAL ADHESIVE FOR THE SURGEON

Plasma clotted with Thrombin produces a natural physiological adhesive which has been used by some surgeons as the basis of a new technique.
In skin grafting, it is now the method of choice. The end results are superior and the operation itself is simplified.
In E.N.T. surgery, important new applications have been described. In general surgery, interesting suggestions have been made.
THROMBIN (MAW) is prepared in our Meriton Laboratories and is stable, standardized, and conveniently packed ready for use.

'BENYLIN' *Expectorant*

The ability of 'Benadryl' to relieve the cough and other distressing symptoms associated with the "common cold" represents still another clinical application of this remarkably versatile drug. 'Benylin' Expectorant not only relieves coughs, but is also effective in alleviating nasal stuffiness, sneezing, lachrymation and bronchial congestion.

Each fluid ounce contains: 'Benadryl,' 80 mgm. Ammonium chloride, 12 gr. Sodium citrate, 5 gr. Chloroform, 1½ min. Menthol, 1/10 gr. In a raspberry-flavoured syrup.

Adult dose: 1 to 2 teaspoonfuls.

In 4, 16, and 80 fl. oz. bottles.

CONFERENCE ON INFERTILITY

FAMILY PLANNING ASSOCIATION

The Sixth Annual Conference on Infertility was held in the Usher Institute, Edinburgh, on September 17 and 18, under the auspices of the Family Planning Association.

Mr. W. SELBY TULLOCH (Edinburgh) opened the first session with a paper on testicular biopsy in the infertile male. He described the technique that he found successful as an out-patient procedure; it was performed under local analgesia, 10% procaine being injected into the spermatic cord and into the scrotum at the site of incision. Suture of the tunica albuginea prevented haematoma formation. In none of his cases did the operation involve absence from work, nor did the patient complain of pain. He showed a series of photomicrographs illustrating the various biopsy findings in subfertile males. In the discussion that followed attention was drawn to the real danger of testicular damage resulting from the *x*-ray treatment of spondylitis ankylopoietica and to the characteristic absence of evidence of inflammation in biopsies from testes which had been the site of mumps orchitis.

Dr. ARTHUR WALTON (Cambridge) spoke next on patterns of male sex behaviour. Characteristic behaviour was not sex-specific, since it was exhibited by the prepuberal male, might persist after castration, and in some species at least was normally exhibited by sexually excited females at all stages of the sexual cycle. The pattern was innate and showed the phenomenon of "drive," which increased in the absence of a normal outlet so that a substitute outlet might be found. Experimental work on rabbits had shown that the threshold of response and degree of completion of the pattern could be expressed as the product of two factors—the sex drive of the male and the excitatory value of the sexual object. That the motor pattern and accompanying reflexes could become highly conditioned to external stimuli was illustrated by a study of the behaviour of bulls during semen collection for artificial insemination; facilitation and inhibition were often observed. The applicability of these studies to human infertility problems was developed in the discussion. The importance of lack of sex drive as an infertility factor was demonstrated, among other things, by the finding of an intact hymen in 5% of "infertile" wives.

Dr. A. G. OETTLÉ (South Africa) read a paper, in conjunction with Dr. G. VAN DRIMMELEN, in which he developed a theory of sperm quality based upon the known facts concerning the development and subsequent loss of the characteristics of motility, ability to fertilize, and ability to ensure completion of embryonic development. There were many gaps in our knowledge, and it was hoped that a consideration of the subject in this way might help to show where further work was needed to fill in some of these gaps. A lively discussion ensued, ranging over many aspects of reproductive physiology.

Ovulation

Dr. G. I. M. SWYER (London) described a method of treatment of anovulatory failure by the cyclic oral administration of stilboestrol and ethisterone. He reviewed the results of this treatment in 40 women in the reproductive years, consisting of 14 case in which the presenting symptoms were prolonged and excessive irregular uterine bleeding, 13 in which the periods were scanty and infrequent, or, if regular, found to be anovular, and 13 cases of secondary amenorrhoea of one year's duration or more. In the first group evidence for the re-establishment of ovulation was available in eight cases, and there were three pregnancies. In the second group the same number of successes occurred, but in the third group no successful results at all could be claimed. The discussion of this report centred around the problems involved in the establishment of the condition of anovulatory failure before treatment and the elimination of spontaneous cure—in other words, the difficulty of ascribing the results after treatment as being indubitably due to treatment.

Mr. ALBERT SHARMAN (Glasgow) read a paper on the re-establishment of ovulation post partum and after abortion. This was a preliminary communication of a wider investigation as yet incomplete. There had been five previous investigations on the re-establishment of ovulation, but all of small series of cases, and there were considerable discrepancies in the results. His own series consisted so far of 628 endometrial biopsies in 283 women post partum and 125 biopsies in 36 women following abortion. Seventeen patients had had more than 10 endometrial biopsies performed during the nine months following delivery. One patient had had 24 weekly biopsies. Mr. Sharman based on this material a full account of the re-establishment of ovulatory cycles and their relation to lactation.

Pelvic Endometriosis

Mr. G. DOUGLAS MATTHEW (Edinburgh) discussed pelvic endometriosis in relation to sterility and showed that fibroids, metropathia haemorrhagica, fixed retroversion, and other conditions frequently coexisted. He considered the possible aetiological significance of social and economic conditions, and of prolonged oestrogenic stimulation without the respite of pregnancy. Diagnosis could be most difficult, especially since the severity of symptoms need bear no relationship to the extent of the disease; laparotomy, therefore, was the only certain diagnostic procedure and was recommended in all doubtful cases. Conservative surgery was the treatment of choice; if this was rewarded by pregnancy and recurrence followed, more radical measures could be adopted subsequently. In the discussion mention was made of the value of hysterosalpingography in the differential diagnosis of endometriosis from the late results of pelvic sepsis, and of the possible value of testosterone as a therapeutic test as well as in preoperative treatment.

Mr. S. BENDER (Liverpool) drew attention to the existence of peritoneal pockets as a cause of sterility. Usually they resulted from pelvic peritonitis, which might or might not have caused tubal damage. Although tubal patency was almost always carefully investigated in cases of sterility, attention was seldom paid to the existence of a clear pathway between the ovary and the abdominal ostium. Obstruction of this pathway, or pelvic block, could be due to the presence of a pelvic pocket in relation to the abdominal ostium—easily demonstrated by salpingography—but it could also be due to the ovary being pocketed away from the general peritoneal cavity.

Disappointed by the results of other forms of treatment, Mr. LINTON SNAITH (Newcastle-upon-Tyne) said that he had been using oestrogens in the treatment of threatened and habitual abortion for the last two years. In threatened abortion, provided it was not inevitable, an initial intramuscular injection of oestradiol benzoate, 10 mg., was followed by oral oestrogen therapy. In habitual abortion oestrogens were given orally, starting a few days after the first missed period. There were 31 patients in this group, and in half of them stilboestrol alone had been used. So far the results were regarded as successful in 25 of these patients, other methods of treatment having previously failed in many of them. There was a surprisingly high incidence of toxaemia of pregnancy in these cases. Mr. Snaith reviewed the possible mechanisms whereby oestrogens could be of benefit, and concluded that there was no evidence that they did harm in pregnancy, while they might be beneficial, especially where "blighted embryo" in the early months of pregnancy was the cause of repeated abortion.

A full discussion followed, and the difficulties of assessing the results of treatment in habitual abortion, as well as its definition, were stressed. Despite their variations in treatment, nearly all who contributed to the discussion secured approximately 80% success. The random distribution of abortion sequences, as in the classical description of Malpas, had to be considered, and it seemed that only extensive controlled series could be expected to show the undisputed value of any therapeutic regime.

Fructose and Fibrinolysin

Miss URSULA PARSONS (Cambridge) described the work she and Dr. T. Mann had done on the effects of testicular hormones on the formation of seminal fructose. Considerable variations in the seminal fructose concentration, both in the same and in different individuals, were found in man and in rabbits. In the latter, however, it was shown that castration was followed by a fall almost to zero in the seminal fructose, while the adminis-

tration of testosterone, both by implantation and by injection, was followed by the rapid return of the fructose to normal levels, from which it fell again on removal of the implant. Stilboestrol implants in intact rabbits also depressed the seminal fructose. Dr. MANN described how the fructose content of the castrated rat's prostate and seminal vesicles could be used as a sensitive indicator of androgenic activity—far more sensitive than the weight change—and it was suggested that this would provide a simple and satisfactory method for androgen assay. As little as 0.05 mg. testosterone could be detected by this means.

Mrs. CLARE HARVEY (Exeter) described a relatively simple method for estimating the rate of liquefaction of blood fibrin by seminal fluid. It was found that the time of liquefaction of a constant quality of fibrin was related to the fibrinolysin activity in a manner expressed by $\log C = a \log T + K$ where a and K are constants, C is the fibrinolysin activity measured in arbitrary units, and T time. A regression equation calculated for 99 points from 30 specimens of semen gave a very good fit for a further 110 points from 45 other specimens. The distribution of enzyme activity was found to be asymmetrical, most specimens having a total activity below 50 units. No correlation was found between enzyme activity, sperm motility, seminal volume, time of continence, and fructose content. The residual viscosity of semen was not closely related to enzyme activity, but it seemed probable that the citric acid, thrombin, and fibrinogen content might be at least as important as fibrinolysin activity in determining the final consistency of the seminal plasma.

At the close of the meeting the future of these conferences was discussed, and their continuation was thought to be desirable. It was also suggested that the time might be ripe for the formation of a society for the study of problems in comparative fertility, both from the animal and the clinical side. It was therefore decided to form a committee, of which Dr. A. Walton and Dr. G. I. M. Swyer were elected joint secretaries, the functions of which should be, in the first place, to arrange for a conference next year and, in the second, to consider and present before the conference plans for the formation of such a society.

THE PROBLEM OF RHEUMATISM

TWO-DAY CONFERENCE IN LONDON

The British Rheumatic Association, which was formed in 1947 to direct public attention to the needs of the rheumatic patient, to promote medical and social interest, and to stimulate research, arranged a two-day conference at Chelsea Town Hall on September 28 and 29. In connexion with the conference an exhibition was held at the adjoining Chenil Galleries, where some 15 firms had stands displaying preparations for the relief of rheumatic disorders, electro-medical apparatus, invalid furniture and transport, and devices for occupational therapy. There were also displays illustrating spa treatment, home and aftercare visiting, and industrial rehabilitation.

Lord HORDER, one of the vice-presidents of the association, who was in the chair at the opening of the conference, said that the B.R.A. was helping to make known the magnitude and economic importance of the problem of chronic rheumatism. Its liaison with the Empire Rheumatism Council, founded 15 years ago, was close and cordial.

Cortisone

Dr. W. S. C. COPEMAN said that from the epoch-making announcement by Hench, Kendall, and others of the Mayo Clinic early this year it seemed evident that an abnormality of one of the constituents of the cortex of the adrenal gland was chiefly concerned in rheumatoid arthritis. Hench, working on the old observation that cases of rheumatoid arthritis got well during pregnancy, and on his own observation that this beneficial change occurred also in the course of certain types of jaundice, arrived at the conclusion that the common factor was the adrenal cortex. In 1947, trying out one of the cortical steroids which Kendall had isolated—compound E—Hench found that with large doses the whole disease process and activity, even in the most severe cases, could be reversed within a few days, though the condition relapsed as soon as the administration ceased.

Compound E was an extremely difficult substance to prepare, even in small quantities, and it had so far been impossible to synthesize it chemically. It was prepared at present by partial synthesis from ox bile, but sufficient quantities for adequate clinical trials would never be made available by that means. It had also been found that if adrenocorticotropic hormone, whose chief function was to stimulate the adrenal cortex, was injected a similar beneficial effect was produced, showing that patients could produce an adequate supply for themselves if forced to do so, but the nature of the lesion which prevented this in ordinary circumstances still remained unknown. This extract was almost as rare as compound E itself; there was a little of it in Europe, he believed, but much of it, so far as he could make out, was inactive.

The problem now to be solved was to produce compound E or any similar substance on a sufficiently large scale to make adequate clinical trials possible. At present only enough was available in the world to treat about 50 persons for a period of a few weeks. The discovery was likely to rank with insulin, and possibly with penicillin, but clinical use was still in the early experimental stage, and it should not be thought of as a practical treatment. The clinical results were manifest: stiffness, anaemia, and joint lesions cleared up; nodules disappeared; weight increased, in some cases so grossly that the patient had to be put on a reducing diet, and the blood picture returned to normal, though not immediately—"travelling," as Hench said, "on the same line, but not in the same train." A warning was necessary against false descriptions of compound E. Vitamin E with something else added had been presented by some vendors in America as "compound E," and therefore it was desired that the substance should not be given that description but should be referred to as "cortisone."

Dr. OSWALD SAVAGE, who, like Dr. Copeman, had recently seen this work in America, said that here again the research chemists had come splendidly to the aid of medicine, as they had done in the work on the sulphonamides and penicillin, and in work also on preparations such as stilboestrol. Those interested in the problem in this country would be greatly encouraged if they could see the excitement which this discovery had aroused in America. This was no mere flash in the pan. It was the result of years of patient research on the physiological side by Hench and his colleagues and on the chemical side by Kendall and his colleagues, both at the Mayo Clinic.

Rheumatic Patients in Rural Areas

Dr. W. S. TEGNER, secretary of the International League Against Rheumatism, said that patients in rural areas presented a twofold responsibility. The doctor must make an accurate diagnosis, and he must also plan his care in circumstances very different from those of a hospital clinic. Each type of rheumatism called for its own treatment, and, moreover, each patient was an individual and must be treated as such. The patient wanted to be told about his own disease and its management, and this was particularly important in the case of the rural patient. At the Mayo Clinic no patient went home without having listened to a series of lectures on his disease. The care of the rural patient was primarily, of course, the responsibility of the local doctor, who might call in a specialist if needed, but specialists in rheumatism were still rare and seldom accessible to the rural patient. Drug treatment of rheumatic conditions was ameliorative rather than curative. A form of treatment acknowledged to be of great value in the management of rheumatic disease and the prevention of deformity was physiotherapy, ranging from massage and exercises to complicated electrical treatment. Domestic physiotherapy was necessary for the rural patient. There was a danger that in modern physiotherapeutic advances it might be forgotten that for many years domestic methods, such as rubbing the part with liniment and applying heat by what would now be considered crude methods, had been highly successful. In the instructions given at the Mayo Clinic the patient, on being

discharged, was told of at least six different methods of applying heat apart from electricity. These included the hot water-bottle, the hot brick wrapped in flannel, the use of the flat-iron, and the like, some of which sounded antediluvian but worked well.

There was a good deal of mystery and misunderstanding about electrical treatment. Very often when a reference was made to electrical treatment no more was meant than the generation of heat. It might be that the rural patient was unable to obtain the ordinary forms of infra-red radiation or short- or long-wave diathermy as used in hospital clinics, but there were domestic substitutes for them which could be most valuable. Altogether, the rural patient presented a problem, an interesting one, which could be largely solved by personal interest and sound advice.

Dr. A. B. Williamson, administrative medical officer of the Leeds Regional Hospital Board, said that a scheme had been worked out for his region whereby nine peripheral clinics were or would be established at various industrial centres, and, as soon as possible, three others so placed as to serve rural areas. To these peripheral clinics, situated in hospitals, the patient could be sent for diagnosis, and if specialist advice was necessary he could be accommodated for a short time in one of a dozen beds. After diagnosis, treatment would be given in the department of physical medicine at the hospital or elsewhere. If treatment was not possible at the peripheral clinic the patient would be referred to the centres—Leeds General Infirmary and the Royal Bath Hospital, Harrogate, and there he might be treated as an in-patient for months. Out-patient clinics had been established in Harrogate, and for the ambulant type of case permission had been obtained from the Ministry of Health to take over a large hotel near the baths, where it was hoped to accommodate up to 160 patients.

Industrial Rehabilitation of the Disabled

The second half of the conference was devoted to the problems of rehabilitation. Air Commodore G. O. Venn gave an account of the progress of "Remploy Limited," of which he is executive director. Remploy Limited, until recently known as the Disabled Persons Employment Corporation, is an industrial undertaking operating factories as much on industrial lines as possible, and aiming to employ in productive work all men and women who are registered at an employment exchange as disabled and who cannot expect to obtain and hold work in open industry. The programme calls for 137 factories, 20 of which are to be specially for the tuberculous. At present the disabled are being employed in 62 factories, and nine more are in process of being staffed and equipped. Over 3,000 disabled are at work in the factories now established. A fair number of epileptics are being employed, also sufferers from diabetes, paraplegia, and cardiac conditions. In South Wales a large proportion of ex-miners suffering from silicosis have gone into these factories. The number of sufferers from rheumatism, including spondylitis, employed is 240. Air Commodore Venn said that they had had a fair amount of success, but they were a long way from covering their first costs. A "homework" scheme was being operated in ten districts, but the difficulty was to find a suitable product which could be made in the home and command a ready market.

Another contribution was by Mr. John Arthur, founder of Michael Works Limited, a woodworking factory, run as an ordinary economic unit, and employing 75% disabled labour. He said that a small proportion of disabled men could be reabsorbed in open industry, but many could not maintain the pace, and it became increasingly evident that small unit factories producing specially selected work were the best answer to the problem of the re-employment of the disabled. The first interview with the employee was the most important part of the rehabilitation process. At that first contact there must be established a positive assessment of the disabled man's remaining powers of working again and earning a living. He should be encouraged to think of what he could do as opposed to what disablement prevented him, in his own view, from doing. Once confidence was established the management must then see that the right job was found for the man.

REHABILITATION

A special clinic with demonstrations was given by Dr. Howard Rusk, of the Bellevue Hospital and the Institute of Rehabilitation, New York University, at the Royal Free Hospital on September 14, with Lord Horder presiding.

Dr. Rusk spoke of the enormous cost, in both wealth and happiness, which was incurred by a failure to secure proper rehabilitation after industrial and other injuries and illnesses. He gave a large number of figures illustrating this point, and then proceeded to demonstrate the various methods which he used. The cases in which he was principally interested were those of hemiplegia, spastic paraplegia, and various types of quadriplegia. If rehabilitation was to take its proper place, a correct diagnosis should be established in the first instance.

He went on to detail the various tasks which make up the routine of life. These tasks were set out on a form and each patient was provided with this form on entering the clinic. As the patient found himself able to complete his own toilet, move from a wheel-chair to bed, and from bed to a wheel-chair, and so on, the blanks on the form were filled in so that the patient could see his progress in pictorial form. So successful had this method of fostering a competitive spirit been, that by means of various mechanical methods even patients who were quadriplegic had been able to return to some method of earning a living and, even more important, had been rendered independent and able to look after themselves.

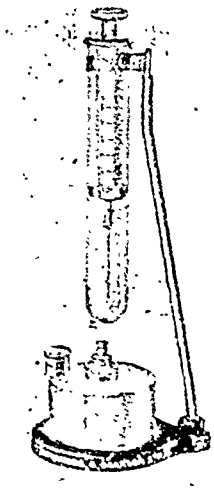
KING'S COLLEGE HOSPITAL MEDICAL SCHOOL

The annual dinner of King's College Hospital Medical School was held at Claridges Hotel on October 1 under the chairmanship of Dr. J. H. Sheldon. The toast of the medical school was proposed in a witty speech by Dr. Wilfrid Oakley. In response the dean, Mr. Harold C. Edwards, referred to the difficulties of admitting students to King's. For some reason or other, he said, medical education was becoming very popular, and there had recently been 900 applications for 50 vacancies. In deciding who should fill the vacancies it was impossible to avoid disappointing some of the sons of King's men. But every attempt was made to assess objectively the qualities of the applicants. In spite of the legal separation between the hospital and the medical school they continued to work in close harmony. The toast of the guests was proposed in a felicitous speech by Dr. Sydney Thomson and responded to by Sir Hugh Cairns, who the day before had given the inaugural address printed elsewhere in this *Journal*. Sir Hugh said that his first acquaintance with King's was through the well-known textbook by Rose and Carless, which he read when a student in Adelaide. He compared this with Osler's great textbook—a source of questions in general knowledge. Sir Hugh said it was a pity that the National Health Service had to be so centralized, and referred sympathetically to the present difficulties of the general practitioner. Dr. Terence East, in proposing the health of the chairman, referred to his contributions on diseases of bone, anorexia nervosa, on the distribution of iron in the body, and now on geriatrics—not so boring as Cicero's *De Senectute*. In reply, Dr. Sheldon said that physicians often died of the diseases they treated, which was why he had become interested in geriatrics.

MIDDLESEX HOSPITAL MEDICAL SCHOOL

The annual dinner of students, past and present, of Middlesex Hospital Medical School was held at the Savoy Hotel on September 30 under the chairmanship of Professor E. C. Dodds. The chairman paid a tribute to the late Mr. Turner Warwick, with whom his own association dated back to the early 'twenties when Warwick was pathological registrar at the Bland-Sutton Institute. They welcomed that evening his son as senior Broderip scholar. Professor Dodds claimed for the Middlesex that it was "undoubtedly the most remarkable of medical schools." It aimed at keeping the basis of education as broad

as possible. There had been many criticisms of the medical schools of London that they were too narrow, but the benefactors of the Middlesex had indicated that it should be a school of research in addition to a school purely for the training of doctors. He believed that this broad administration, started by Sir Charles Bell Bland-Sutton and encouraged by Lord Webb-Johnson and others, had been well justified.



Dr. H. E. A. Boldero, dean of the school, said that looking back on the year, although it was the first year of the National Health Service and of the school's charter, he felt that extraordinarily little had happened. That was as it should be; changes should be slow and deliberate. He went on to refer to the retirement, due to take place on the morrow, of Professor John Kirk from the Courtauld chair of anatomy. Another figure they were losing, and one who had contributed greatly to the school in a different capacity, was Mr. R. A. Foley, the school secretary, who was retiring owing to ill-health. The school had appointed a woman as his successor—Miss Eileen Walton. Another Middlesex man of whom they were very proud was William Sladden. He qualified two or three years ago and was medical officer on an expedition to the South Pole. The expedition met with disaster, and Sladden's heroism and endurance under trying circumstances had earned high praise.

Mr. R. Turner Warwick, senior Broderip scholar, in responding to the toast of "The School," gave an account of athletic activities during the year. The evening ended with the drinking of the health of the chairman, proposed by Dr. G. E. Beaumont, who spoke of Professor Dodds out of a friendship which dated back to the time when Dodds came to the Middlesex as a student with "the valuable technique of passing every examination with distinction."

Preparations and Appliances

TEST-TUBE STERILIZER FOR SYRINGES

Dr. H. F. Barnard, Pathologist, Westwood Hospital, Beverley, E. Yorks, writes: Sepsis from an unsterile syringe procedure is not uncommon. The method here described offers a simple way to boil a syringe and handle it dry. It is speedy and can be used readily anywhere—for example, in the home—though it is appreciated in the surgery or ward.

A syringe of the glass plunger type rests in a glass boiling-tube, this being supported in a spring-clip stand over a spirit lamp. On lighting the lamp the water boils in 60 seconds and the syringe is surrounded by steam, whilst boiling water passes up the needle and barrel. Trials show that five minutes' boiling is sufficient. Normally a syringe is washed clean, but as a more searching test serum heavily infected with *Staphylococcus aureus* was allowed to dry on the plunger and in the barrel. After boiling for five minutes in the tube no growth was obtained from washings. Nevertheless it is important that the syringe should be used only for aseptic purposes.

When sterilized the syringe is lifted out by the handle, and the outside dries in a few moments. This avoids the risk of contamination spreading to the needle from the hand on a wet barrel. It is convenient to carry the syringe about in the tube after tipping out the water. If left in the tube the syringe remains sterile many hours. A useful protection of the needle-point is achieved in this method.

I would like to thank Mr. A. A. Ralph, of Reynolds and Branson, Ltd., of Leeds (the makers), for help in producing the apparatus.

Correspondence

The Innocence of Deans

Sir,—How stirring are the times in which we live. Never have learned doctors so bedevilled each other since the robustious days of the seventeenth and eighteenth centuries. The medical press is a free-for-all, with no holds barred and no non-combatants. The most innocent and peaceful observer who cautiously raises his head above the sandbags is liable to receive a shattering volley from all sides. So when Dr. Geoffrey Bourne (September 24, p. 704), a redoubtable slinger of verbal brickbats, is pelting Dr. H. E. A. Boldero with great gusto (in the hopes perhaps of winging another distinguished shadow he glimpses behind) a sudden association comes into his head and with one tremendous backhander he demolishes the whole damnable denomination of deans, men whose "whole outlook and training is one of honest and faithful subservience to an institution," incapable of defiance of authority.

Let authority take note of this testimonial to decanal innocence. So will we the better preserve in these difficult times the integrity of the institutions we subserve.—I am, etc.,

London, S.E.1. E. R. Boland.

Distinction Awards

Sir,—In your issue of September 24 (p. 704) Dr. J. W. Linnell's comments upon my letter (September 3, p. 545) suggest that he is under some misapprehension, arising in part from the condensation of my original letter to you in which I defined "postgraduate teaching hospital" so as to include "all those medical schools recognized as preparing candidates for the higher qualifications," while undergraduate teaching hospitals were defined as "those not preparing candidates beyond the qualifying examinations." The marks printed are the average of a few colleagues' markings and are included only as an indication of how the idea may be worked out.

I am careful to leave it to the Awards Committee to amplify and modify the scheme, and I suggest that every consultant should mark the Awards Committee's scheme in detail, that these marks should be averaged by a firm of accountants, and that the average markings should be binding on the Awards Committee. Thus Dr. Linnell—in common with every other consultant—would have the chance to record as many "0s" as he pleases, "to put down the mighty from their seat and to exalt the humble and meek." Others will join him in recording a "0" for "officers of academic medical societies," but some wished it to be included.

Another point obscured by the condensation is that while the averaged detail marking of Sections 1 and 2 would be final—each candidate scoring in each subsection the highest mark to which he is entitled—the marking in Section 3, "Publications," would not be greater than the averaged figure, but might be as little as 1%. I believe that a representative committee of each consultant group could mark each candidate on his application under this heading in a matter of minutes. Personally I shall be content if a man whose original work is outstanding scores as many marks for it as for "15 years of service on an undergraduate teaching hospital"—we are required to assess Distinction—but once again Dr. Linnell may put down what figure he likes. His statement that the scheme "attaches no value to such vexatious and intangible considerations as clinical acumen and judgment, or operative skill," is surely frivolous. If a consultant's senior hospital appointment and the years of service he has given to that post and to others leading up to it are not a criterion of his "clinical acumen, judgment, and operative skill" then we must indeed abandon hope of solving this problem, for every appointments board before whom he has appeared has sought to assess, after full consultation and deliberation, just those things.

The Awards Committee is required to carry out certain duties which were defined by the Spens Committee, approved by the profession, and then—and only then—passed into law. Apart

from abstention, the time has gone by when we can do other than assist the committee in their thankless task. I have sought to put into words an idea which may prove helpful. The Awards Committee decides what factors contribute to the idea of distinction, and the consultants as a whole decide, democratically, what marks are to be attached to those factors.—I am, etc.,

London, W.1. FREDERICK RIDLEY.

SIR,—Those of us who have read and admired the writings of Dr. F. M. R. Walshe appreciate the courage, wisdom, originality, and sincerity of his contributions to medicine. He is an acknowledged leader in thought, fittingly recognized. Yet in spite of this, or perhaps because of it, we see him running counter to the controlling political and academical authorities of the day. Surely he must be given the distinction of being called a "reactionary," a "difficult fellow," or, by those who fear him, "naughty," for these are the terms in which we honour the leaders of our time. Mr. Winston Churchill has been so distinguished in the House.

Let Dr. Walshe not fear that he is without support from graded specialists, for many of them now realize that their previous failure to interest themselves in the nomination of, and voting for, political and academical leaders has cost them very dearly. The members of the profession voted with a solidarity previously unknown against this set-up, but that was when few realized the enormities now beginning to be revealed to them. I venture to suggest that if the planners had clearly shown their designs, and the humbug attaching to them, a far greater solidarity against them would have resulted which would have been maintained in spite of the leaders; and the public would have benefited.

Dr. Walshe (September 17, p. 649) states, "The power of money is great." He realizes that local influence is to be used and is feared, that the awards are in the power of the planners with sycophants as satellites. These hate criticism and have designed their set-up to keep out the "difficult fellows." They are steadily acquiring a dictatorship which threatens not only the "distinction awards" but the very liberty of the doctor. The writings of the workers will have to be submitted to powerful dictatorial overseers who will so secure their "notice": failure to do so may mean rejection or even a blasted career. At the moment one of our leading surgeons can state, "I personally suspect the man with huge figures and a negligible mortality of being a surgical spiv," but how long will the critic of statistics be so tolerated? Canvassing for votes with intimidation, or even instruction, for high distinction or office in the profession already exists, and woe betide the "difficult fellow." As I overheard the conversation, "He's probably the best man we have on the staff; but why, why, why does he keep that imp on his shoulder?" Criticism, however justifiable, of the scientific or political activities of the powerful—the life essence of a progressive profession—will become difficult—yes, and hazardous—to the career of the critic.

Speaking as a radiologist, prior to this service radiologists kept their liberty by earning their living with their own units to the benefit of their patients and the Exchequer and with credit to the profession. Their private apparatus, at a time when the country is financially embarrassed, has to all intents and purposes been scrapped, while the hospitals are clamouring for more and more equipment (though probably adequate to do reasonable requirements) and the manufacturers with stores filled with units await "instructions." By the time the units are supplied they will be out of date. But even to mention such matters may jeopardize a "distinction award."—I am, etc.,

Birmingham. JAMES F. BRAILSFORD.

Medical Education

SIR,—There were several most interesting articles in the educational number of the *Journal* (September 3) on aspects of medical education, and although some time has elapsed since they appeared I hope I may be allowed to comment on them. I feel that this is the more needful in that they imply that there is only one kind of approach to medical education, an approach which might be summed up as more courses, better courses, or linked courses. I shall confine myself to two lines of criticism.

The first criticism is of all this talk about scientific method. It seems to be hoped that, by reading scientific textbooks and attending systematic courses of lectures in different branches of science, scientific method will somehow be inculcated. Such courses are doubtless important for the student of science, but surely he does not acquire scientific method from them. They are aids in dealing with actual problems of science and sometimes may suggest them. But scientific method surely starts with the recognition of a problem and consists in the isolating of it from irrelevances. It is in fact a kind of interrogation in which the framing of a question is of great, possibly of paramount, importance. Its affinity with clinical examination is obvious, but there is no closer relationship between scientific method and clinical examination. The objects of each are too diverse.

While it is an attractive ideal that every doctor should be trained in scientific method, I venture to suggest that it is neither an essential nor even a possible one. The problem for medical educationists therefore resolves itself into that of how much of the enormous corpus of knowledge in biology and its derivative sciences should be insinuated into medical students.

The second criticism refers to the question of skill in medicine. Professor W. Melville Arnott (p. 497) asserted in his address that medicine is essentially a science—"is an art only in so far as the term means human skill." An art in this sense, and in most senses, is capable of being taught to a very considerable extent. In music and the pictorial arts this is recognized by the establishment of schools for the purpose. It was therefore disappointing to find in an address on reform in medical education no reference to attempts to improve "human skill" in the practice of medicine. Surely it is not considered that the human skill of the newly qualified graduate is as high as it should be. There are certain aspects, notably in the practice of asepsis, where nursing education is superior to medical.

One is tempted to develop this theme further, but I shall content myself with the suggestion that in a revival of apprenticeship lies the most hopeful path for progress in medicine. Such an apprenticeship, served mainly in hospital and begun early in the medical curriculum, not left to an intern year at the end, will itself enable the student to learn from his lecture courses. Such close acquaintance with the material of the subject studied has been the condition determining the progress of the whole scientific movement; it seems the most likely method of developing a genuinely scientific outlook in those medical men temperamentally capable of it. But it will require all the hospitals in this country to provide such an apprenticeship. The persistent separation of teaching hospitals from all others would have to be abandoned and some type of union of boards of governors with regional hospital boards set up. On other grounds, mainly administrative, this has already been mooted. One may hope that it will be speedily achieved.—I am, etc.,

Heswall, Cheshire. DAVID WILKIE.

Teaching of Physiology

SIR,—In discussing the imperfections of the practical training in physiology (September 3, p. 502) Professor G. W. Pickering makes the following statement, "Classes in mammalian physiology in Great Britain will be difficult to organize so long as they are based on the cat or dog, uncommon and expensive animals the use of which is much hedged round by restrictions," and he goes on to cite the example of Adelaide, where wild rabbits are used which are tough and cheaply trapped. One is left with the feeling that the problem of animal supplies in this country exists only because of the lack of resource on the part of British physiologists in failing to discover and trap some suitable British mammal. Might I correct this impression by some brief comments on the statement which I have quoted above?

1. Expense is not the deciding factor in making a choice between cats and rabbits. Current prices are: rabbits, 10s.; cats, 10s. to 15s. Even Australian rabbits imported would not be likely to be much cheaper.

2. Uncommon is not the best word to describe animals whose occurrence is indicated by figures taken from the report of the Sheffield branch of the R.S.P.C.A. as reported in the *Sheffield Star* (June 15, 1948). According to this, during the previous year 10,531 cats and 5,777 dogs were destroyed in Sheffield (pop. 476,360). If these figures are typical for the whole country about 1,000,000 cats and 500,000 dogs are destroyed annually in Great Britain.

3. The restrictions mentioned by Professor Pickering are hardly relevant, since the use of any vertebrate (except the human being) is subject in this country to restrictions very similar to those on the use of dogs and cats, and these restrictions would certainly prohibit such interesting experiments as Professor Pickering describes in Australia. On the other hand the use of decerebrate cats is not hedged around by these restrictions, and Professor Pickering must know of the standard textbook (*Mammalian Physiology*) of Liddell and Sherrington, using decerebrate cats.

4. No other animal, human or otherwise, known to me and available in this country at any price can entirely replace the dog and cat for teaching and illustrating many of the fundamental principles of physiology, and if Professor Pickering knows of any such animal I and doubtless other physiologists would be grateful to learn about it.

The real obstacle to improving our mammalian physiology courses has been missed by Professor Pickering. It is simply to make available a tiny fraction of these odd million cats and dogs, unwanted and of no commercial value. The problem is ultimately to convince the ordinary kind-hearted and animal-loving citizen that these animals could be of enormous value to medical training and medical progress and, further, that killed individually by trained physiologists under conditions carefully supervised by the Home Office these unwanted creatures are likely to meet a more merciful end than by mass extermination in lethal chambers.

The physiologists, who might be thought to have a not completely unselfish interest in the matter, have hitherto failed to get their point of view accepted by those in authority, and what is needed is a wider recognition of the problem by those interested in medical education but not directly concerned with the teaching of physiology. It is, therefore, a great disappointment to me to find such a lack of appreciation of the problems of British physiologists by one so closely in touch with physiology and so deeply concerned with the whole problem of medical education as is Professor Pickering.—I am, etc.,

Sheffield. D. H. Smyth.

Thymectomy in Myasthenia Gravis

Sir,—Mr. Geoffrey Keynes's account of his 155 thymectomies (September 17, p. 611) will have been widely read with deep interest. The successful accomplishment of this major operation on so many patients implies surgical skill of the first order. When we turn to the results we are naturally disappointed, as Mr. Keynes must be, that it is not yet possible to select those most likely to benefit from surgery. It seems that a thymoma is unfavourable, but we are otherwise in the dark.

The significance of this big experiment is so important that we must be wary of any possible flaw in its interpretation. A comparison of neostigmine dosage before and after the operation is a useful criterion when the difference is great—Mr. Keynes's groups A and B—but in those with only slight improvement it may well be falsified by the patient's attitude to the drug. For instance, a patient advised to reduce the dosage, and sometimes to stop taking the drug because it is thought by her advisers to be dangerous, will obey and lead a less active life or, more often, make a false return to follow-up inquiries. This is no idle speculation; I know it to be true of some patients.

A second difficulty in assessment concerns the time lapse allowable between the operation and the beginning of improvement. Surgery must surely set itself reasonable limits in this respect. It is difficult to give credit to the operation for a result that is not seen for, shall we say, three months. This time lag is not made clear by Mr. Keynes.

Although I have been unfortunate enough to see six failures in consecutive thymectomies in my patients I am certain that remarkable and unusual remissions have taken place in many cases. Dr. Viets, whose 250 patients at his Boston clinic make him the most experienced student of this disease, tells me that he is satisfied that surgery has been followed by rapid improvement in some patients he had known for years and who had shown no previous good remission.

We are still entitled to speculate on the cause of the more numerous failures. Can it be that myasthenia gravis is a label covering a number of disorders of the myoneural junction? Every functional unit of the neuromuscular system has its own varied pathology—cortex, pyramidal tracts, anterior horn cells, and peripheral nerves are vulnerable in their several ways. Is it not, *a priori*, likely that the myoneural junction, susceptible to curare and in "myasthenia," can be impeded in more ways than we know? Sheldon and Walker (*Lancet*, 1946, 1, 342) have shown that the condition I have called acute thyrotoxic bulbar palsy, in which neostigmine response is striking, can be cured by thyroidectomy.

In future assessments we would do well to remember that recovery from a severe myasthenic state, however striking to behold, is not in itself a reliable criterion. Experienced workers in this field will agree that remissions are more common in the acutely afflicted than in those with a mild chronic course. We need an analysis of results in patients known for their previous even behaviour. Such figures, which I hope Mr. Keynes can abstract from his records, would give a better idea of the effect of thymectomy than we could ever obtain from a large unselected series.

Mr. Keynes's stimulating lecture raises another subject. Clinical and biochemical studies of this large group of thymectomized persons must surely yield some clue to the function of the thymus. We may hope that this new operation will advance our knowledge of this organ, just as the work of Reverdin and Kocher helped to open up thyroid physiology.—I am, etc.,

London, W.1. L. P. E. Laurent.

Gravitational Ulcers of the Leg

Sir,—My paper on the aetiology of gravitational ulcers (August 27, p. 458) was based on 270 patients seen personally in the skin department of the Leeds General Infirmary. The series included every patient that I saw with this condition during two and a half years, and for this reason the term unselected was applied. These patients had ulcers present for a period varying from a few weeks to many years. A number of them had been referred before treatment by surgeons on the staff of the infirmary and from the varicose-vein clinic. The series seems to me to be representative, and my findings are not markedly different from those of Bauer working in a surgical clinic.

Dr. H. S. Russell's description (September 10, p. 598) of my series bears no relation to the facts as given in my paper, and his feeling that I have "seen the failures and should study the successes" before coming to a conclusion is as unjustified as it is unreasonable. My paper was concerned with the cause and not with the treatment of these ulcers. Hence, of those patients whose varicose veins had been injected, only those in whom this treatment seemed to be the direct cause of their chronic venous stasis were mentioned.

Mr. H. J. Croot (September 17, p. 654) does not quote me quite completely. I wrote, "The concentration on treatment of superficial varicose veins in patients with venous stasis is neither rational nor useful. . . ." The point I wished to make was that if varicose veins are present in a patient with venous stasis with or without ulceration, all too often treatment is concentrated upon them and not upon the fundamental cause of the condition—namely, a deficient venous return from the whole limb. While I am perfectly aware that treatment of such varicose veins may in a few carefully selected cases benefit the ulcers, yet in others injection of such veins may intensify the chronic venous insufficiency already present, possibly by causing thrombosis, not only in the superficial varicose veins but also in the third system to which Mr. Croot refers.

The problem of aetiology must be solved before treatment can be rational, and more about both, I feel sure, will only be learnt by co-operation between surgeons, anatomists, pathologists, radiologists, and physicians, and only if the broad view of the circulation of the lower limb taken by your annotator (August 27, p. 480) is adopted.—I am, etc.,

Zurich. S. T. ANNING.

Transmission of Syphilis

SIR,—Dr. A. O. F. Ross (April 10, 1948, p. 691), writing on the transmission of syphilis, reached the conclusion that "the advice that should be given to an adequately treated male is that he should not attempt to procreate children until five years after the date of infection." A case of a man and his wife seen recently by me seems to confirm this.

A woman, aged 27 years, was referred here late in pregnancy with two positive blood Wassermann reactions, which had been taken as routine—the second, of course, to confirm the first. She had no signs or symptoms. About a year previously, while living elsewhere, she gave birth to a baby, of whom her husband was the father, who developed a rash on its palms and soles soon after birth and who died of "pneumonia" when two months old. There can be little doubt that the child had congenital syphilis. The mother had not had a blood Wassermann reaction done during this pregnancy, which was her first.

All the facts of the husband's history have been confirmed. The diagnosis in his case was primary syphilis, sero-negative; on March 20, 1944, and on the following day dark-ground examinations of serum expressed from the sore in the penile sulcus were positive for *T. pallidum*. His blood Kahn test on March 20, 1944, was negative, and the Wassermann reaction on the cerebrospinal fluid was also negative three months later. He had adequate treatment for a year, and subsequent blood Wassermann reactions and Kahn tests were all negative.

He returned to England after military service on December 1, 1945—i.e., about one and three-quarter years after infection. He became engaged to the girl who is now his wife in 1946, when he had intercourse with her for the first time; they were married later in that year. (This story is confirmed independently by the husband and wife.) Her baby was born in 1947, and, as I have said, this baby died aged 2 months of probable congenital syphilis.

The wife told me that she had never had intercourse with anyone except her husband and that there was no previous family history of syphilis. She is one of six children, all living, as are her father and mother. She was an in-patient in a sanatorium for eight months in 1942; the medical superintendent writes me that she had "a tuberculous pleural effusion. There was no suggestion at that time of her having syphilis, so no blood Wassermann reactions or Kahn tests were done." The husband's blood Wassermann reaction and Kahn test were both negative on two occasions a few months ago.

Of course, we can never disprove that the wife had not had syphilis before she was married, but this is very unlikely, and the probability is that she was infected by her husband.—I am, etc.,

Barry, Glam. PHILIP SIMON.

"Acute Abdomen" in Diabetes Mellitus

SIR,—Though one reads of the "acute abdomen" of ketosis[1] and sees it referred to as a differential diagnosis by Zachary Cope,[2] it is not often that one is confronted with this problem.

On September 12 a man of 24 years was brought to hospital as an acute abdominal emergency. He was writhing in agony with abdominal pain and continuously crying out to be given something to relieve his pain. The history was that 18 hours previously, following a bout of vomiting during which, in the course of an hour, he vomited about five times, he was seized with abdominal pain. The pain persisted and had increased in intensity since the onset. The description given by the patient of the pain was that it felt as though he was "breaking in two." He was sure it was not a colicky pain. The pain was confined to the abdomen. He was quite definite that the vomiting had preceded the pain. Lawrence[3] mentions this latter point as an aid to diagnosis. It transpired that the man had been a known diabetic for three years and was on 54 units of insulin daily, with a calorie intake of 2,500 a day on a line diet regime. He had run out of insulin three days prior to admission, but continued to eat and had not made any great effort to obtain a further supply of insulin.

On examination, he presented the picture of an acute abdominal catastrophe, with a drawn, anxious, pale look, a dry, coated tongue, subnormal temperature, and a pulse rate of 120 a minute. There was a strong smell of acetone from his breath. The abdomen was held rigidly but with persistence, and between paroxysms of writhing it was apparent that there was no true rigidity. No definite tenderness could be elicited, peristalsis was heard evenly in all areas, liver dullness was present, and rectally no abnormality was discovered. The urine contained a large amount of sugar, acetone, and acetoacetic acid. The urinary chlorides were 1 g. per litre and the urinary diastase was 2 units. While being examined the patient complained of severe thirst, and when permitted to do so drank 1½ pints (850 ml.) of water without pause.

Despite the picture of acute catastrophe, it was not felt that an acute abdomen of so many hours' duration could be possible with so little in the way of definite physical signs, and it was considered safe to give morphine ¼ gr. (16 mg.). Immediate treatment of the hyperglycaemia was instituted, and an intravenous saline drip commenced. Quite soon afterwards the patient quietened down, showed the typical air-hunger respiration of ketosis, the pain disappeared, and the abdomen became flaccid and free of tenderness in all areas. He made an uninterrupted recovery once his diabetic condition was stabilized.

It is regretted that in the urgency of getting the patient controlled no blood estimations were done. It is felt that the nature of the abdominal condition was comparable with that seen in uraemia. I know of no explanation of the "acute abdomen" in ketosis, and I would be very interested to hear of one.

—I am, etc.,

London, S.E.5. M. GLICK.

Pavlov and Conditioned Reflexes

SIR,—Pavlov studied conditioned reflex salivation. If one generalizes by using the word "behaviour" one may bracket in two different ways and say either that he studied conditioned behaviour or that he studied conditioned reflex behaviour. These generalizations are not identical, but many writers in referring to Pavlov's work appear to believe that they are.

Most of Pavlov's concepts appear to me to be labels lacking all reference to process. It enlightens no one to be told that when King Alfred let the cakes burn his sense of smell was inhibited at the time by virtue of inhibition.—I am, etc.,

London, E.13. W. THOMSON BROWN.

Treatment of Ringworm of the Scalp

SIR,—The search for an alternative to *x*-ray epilation of the scalp for the treatment of tinea capitis continues, and the recent article on this subject by Drs. H. Haber, R. T. Brain, and Mr. J. W. Hadgraft (September 17, p. 626) shows no doubt a step in the right direction. Yet it seems that due warning about the relative ineffectiveness of their salicylanilide in carbowax preparation when compared with *x*-ray epilation was not given. The practitioner may therefore be inclined to the belief that an alternative is almost at hand.

In the first place it would seem very wrong to utilize cases of *Microsporon felineum* infection of the scalp to prove the efficiency of any local application. Such infections usually undergo spontaneous cure within months even in the absence of any severe inflammatory reaction, and in their group of 20 cases (including seven showing an inflammatory reaction) a 75% cure rate after anything up to 14 weeks' treatment is very little better than one would expect with no treatment at all.

The single case of *Trichophyton sulphureum* infection did not, of course, respond to treatment. We are therefore left with an uncontrolled series of 6 cases of *Microsporon audouini* infections of the scalp. Unfortunately the duration of infection in each case before treatment was started is not stated. From a study of scalp ringworm in Northern Ireland it has become apparent that about a quarter of all cases of *M. audouini* infections of the scalp undergo cure in less than 6 months if left entirely without treatment (91 out of 374 cases in one localized epidemic. Facilities for *x*-ray epilation of this number in addition to cases from a large epidemic in a second centre were not immediately available, and these cases had

to be kept under surveillance until facilities became available.) In addition, a number of our cases have been successfully treated by manual epilation under Wood's light at weekly or twice-weekly intervals. Manual epilation with forceps can be little better than scrubbing with a nail brush every morning for weeks on end. When viewed in the light of these facts four successful results from six cases is not very encouraging.

A trial of a number of local applications has been made by us in some cases of tinea capitis. Fourteen cases have had a salicylanilide in carbowax preparation with instructions to "rub in thoroughly night and morning to the entire scalp after cutting the hair short." The results are still only provisional, but they are sufficiently discouraging for us to have abandoned use of this particular preparation except for purposes of completing the clinical trial. Of the 14 cases no less than 4 have so far developed a severe contact dermatitis (after 2, 2, 8, and 8 weeks' treatment). Actually this brought about cure in all four cases—but the method is not to be recommended! Dr. Haber and his colleagues do not mention the possibility of local reactions.

Articles such as the one under discussion are of certain theoretical value so long as the impression is not left that local applications alone have already an important place in the treatment of scalp infections due to *M. audouini*. It is often only with difficulty that one succeeds in obtaining permission from the patient's parents (and the family doctor) for *x*-ray epilation. The only effective way to prevent epidemics is to epilate cases immediately they are seen. Failure to do this resulted in our 374 cases in one small centre. A satisfactory *x*-ray epilation carried out by an experienced *x*-ray therapist results in freedom from infection within 4–6 weeks and allows the child to return to school, etc., without being a potential danger to the community. No effort should be spared to make these points with practitioners, who, after all, see the patients first.—We are, etc.,

J. Martin Beare.
Ivan H. McCaw.

Belfast.

Massage with Adrenaline

Sir,—My attention has recently been called to a circular which is being sent "to the Medical Profession only," claiming that a proprietary preparation alleged to contain adrenaline, and exhibited by inunction, has beneficial results "in all forms of rheumatism." The circular is plausible enough at first sight, for it suggests that adrenaline stimulates the production of Kendall's Compound E; and at a time when the dramatic outcome of Hench's work with Compound E is familiar to your readers some of them may be led to prescribe the preparation advertised in the circular.

Nobody would wish to decry the value of physiotherapy in rheumatic disease. But I feel that a few words of caution may not come amiss to those who are not actively engaged in clinical endocrinology. (1) The quantity of adrenaline in the preparation is not stated. (2) It is doubtful how much adrenaline is absorbed by inunction, and whether the effect of adrenaline so absorbed is more than transitory. (3) There is no evidence that adrenaline absorbed through the skin stimulates the production of Kendall's Compound E.

In brief, this preparation only advertises itself by a series of conjectures and hypotheses, and I should advise medical men to steer clear of it.—I am, etc.,

G. L. Foss.

Bristol

Hypnosis in Treatment

Sir,—Dr. K. M. Hay (September 17, p. 653) writes, "The mind is then influenced on the feeling level and to a lesser degree on the intellectual level by the hypnotist: in effect we may say that the hypnotized subject is to a great extent depersonalized." For psychologists and psychiatrists depersonalization means a condition in which the subject is continuously compelled to doubt the reality of his own experiences. Lest we should be accused of restricting to our own use a word which has previously been used in a wider sense, may I quote the passage in which this term was first used? "Cet état dans lequel le moi sent ses actes lui échapper, et lui devenir étrangers, j'appelerai une alienation de la personnalité, ou dépersonnalisation" (Dugas, L., *Rev. Philosoph.*, 1898, 45, 501).

This word, referring as it did to a syndrome with which psychologists and psychiatrists had long been familiar, has since been freely used by French, German, British, American, Spanish, and Italian writers. It has done good service for half a century in this sense. To use it in another would be to debase its value and lead to confusion.—I am, etc.,

London, S.W.3. D. S. Macphail.

Essential Hypertension in Pregnancy

Sir,—Professor J. Trueta (September 17, p. 650) has forestalled me in replying to some of the points mentioned by Mr. R. H. Paramore in his letter (August 27, p. 486), but I should like to add something by way of comment on the latter's second two paragraphs.

Mr. Paramore explains the re-establishment of urinary flow under spinal anaesthesia as consequent upon the fall of blood pressure. Hingson, however, whose experience in this particular field is probably unique in its extent,[1] finds that it is often necessary to withdraw the spinal anaesthetic for a while and to give the patient ephedrine in order that the anuria may be relieved—i.e., that urine begins to be passed as the blood pressure rises and not as it falls. He is not averse to this phenomenon being explained as due to a differential action of the sympatheticomimetic drug, the renal vessels being less responsive than certain others to it, so that the general rise of pressure sends more blood through the former.[2] Such differential action is also the basis of the "order of sacrifice" which was advanced in 1947 by Professor Franklin[3] and has since been supported by further, as yet unpublished, experimental evidence obtained by him and by others, myself among them.—I am, etc.,

London, W.1. John Sophian.

The Backward Child

Sir,—The school holidays just passed have brought the usual mass of school-children for advice because of school failure who are found on investigation to be backward because of a specific difficulty in reading and spelling depending on cross laterality of hand and eye dominance. The most serious cases seem to be the left-eyed and right-handed, but left laterals, with left dominant hand and eye, are only a little less serious.

This form of word-blindness is responsible for so much apparently unexplained school failure—the children "who could do better if they tried"—that it merits much greater attention. The condition is well recognized. It has been described by Sir Henry Head in his book on aphasia, Sir Cyril Burt in *The Backward Child*, Professor Schonell in *Backwardness in the Basic Subjects*, and in many papers in the journals. In America a great deal of research has been done on it. It is essentially a physical problem, but, as failure and frustration are gradually felt by the child, secondary psychological effects appear. Then loss of confidence, feelings of incapacity and social inferiority, and sometimes wild behaviour and even delinquency follow. Games needing co-ordination of hand and eye also suffer, and bring an added feeling of futility. These secondary symptoms usually develop when the child passes 10 years and begins to be self-conscious and to compare his attainments with his own ambitions and the achievements of others. Until then he has usually just been called lazy, or stupid, or inattentive, or "not trying," and he accepts the criticism.

The remedy is to ease educational pressure on reading and writing, to avoid criticism, to make the education as far as possible verbal instead of graphic, and to increase self-confidence through activities which give success. The difficulty usually fades at adolescence, and if the education has been kept at a reasonable level and discouragement avoided there should be little trouble after that.

Three or four months may yet pass before the chilblain season is at its height. But *active* anticipation of the wintry weather can make the future a great deal brighter for those inveterate chilblain cases. Started now, a daily routine of four Ostocalcium Tablets will make an essential contribution towards the healthy capillary circulation so vital in withstanding the cold. Ostocalcium exerts a controlling influence on the permeability of the capillaries, preventing the exudation of fluid into the tissues that causes the characteristic swelling and inflammation. And the Ostocalcium formula takes full account of the need for vitamin D in calcium therapy, each tablet containing 500 i.u. of the vitamin with 125 milligrams of calcium.

A NEW INHALATION ANAESTHETIC

"NEOTHYL"

Brand of

METHYL N-PROPYL ETHER

Methyl n-propyl ether (under the name "Metopryl"), tried clinically in America with favourable results, has now been manufactured by us in this country and given clinical trials under our brand name of "NEOTHYL."

From preliminary reports this ether appears to show certain advantages as an anaesthetic over diethyl ether, and we will gladly send samples for clinical trial to any anaesthetists interested.

LAWS OF MEDICINE

Courvoisier's Law

"In obstruction of the bile duct by a stone, dilation of the gall bladder is rare, the organ having already been rendered fibrotic. In obstruction from other causes, however, dilation is common; fibrosis occurs in only 1/12 of these cases."

LUDWIG COURVOISIER, *born in 1843 at Basle, Switzerland. Professor of Surgery 1888. Noted for his contributions to the surgery of the biliary tract. Died in 1918.*

FAMILIAR TO DOCTORS since their student days, Courvoisier's Law defines two useful though not invariable rules.

Just as the laws of medicine may be qualified by later experience, so there can be no finality in the sphere of drug manufacture. The Boots organisation is alert to every possibility for new developments, and behind its great resources for research and production there is a long tradition of service to the medical profession.

For Gastric or Duodenal Ulcer

IN view of the increasing adoption of intensive alkaline medication for gastric and duodenal ulceration, the selection of a suitable antacid agent is a matter of considerable importance to the general practitioner.

'Alocol' allows of antacid therapy in a particularly effective, safe and reliable form, and replaces with advantage mixtures composed of sodium bicarbonate, magnesia, bismuth, etc. It does not produce any unpleasant secondary reactions, even when taken in large doses and over a long period of time.

Alocol' neutralizes excess gastric acidity to the most favourable degree without provoking the danger of alkalosis, thus producing a markedly soothing effect on the gastric mucosa with the prompt relief of pain and discomfort.

'Alocol' is available in the form of Powder, Tablets and Cream.

Powder—*The normal dose is 1 gramme before and after meals.*

Tablets—*Each tablet contains Alocol, 0.5 gm.; P. Sacch. Alb., 0.4 gm.; Cocoa Powder, 0.035 gm.; Excipient, q.s.* The normal dose is 2 tablets before and after meals.

Cream—Formula: *Alocol 6.0 parts approx.; Glycerin 5.0 parts; Ol. Menth. Pip. 0.005 parts; Aq. Chlorof. 4.0 parts; Aq. Dest. to 100.0 parts. The normal dose is 1 to 3 teaspoonfuls between meals and at bed-time.*

ALOCOL

Colloidal Hydroxide of Aluminium

Chemical history of 'Alocol' with clinical reports and trial supply sent free to physicians on request.

2 ways to better results

STANDARD

Ensign "Standard" X-Ray film gives outstandingly good results in Radiography of the lungs. Its fine definition, good contrast and freedom from fog are greatly appreciated in this branch of radiography.

RADOS (NON SCREEN)

Orthopaedic Radiography requires the extra speed and full gradation of Ensign "Rados" non-screen film. Like all Ensign X-Ray film it is extremely flexible, giving exceptional latitude in the matter of exposure on varying types of equipment.

The essence of prevention is to recognize the condition when the child is learning to read and give skilled tuition then, remembering that the child, however intelligent he may be, will be slower in learning the use of the written symbol than his fellows but that he will, with care, ultimately master it.—I am, etc.,

London, W.1. WILLIAM MOODIE.

Old Age

SIR,—Your correspondent Dr. J. Rushworth Lund (October 1, p. 758) complains of the number of old people who have grown selfish and useless, and suggests that as they eat food and require attention they should be quietly put to perpetual sleep.

This is a brutal proposition. There are, of course, selfish old people, but they are the exception rather than the rule. I could show Dr. Lund large numbers of the aged who are unselfish, kind, and thoughtful, who still do good work, and who are loved by those with whom they come in contact. I would remind him there are plenty of examples of selfish, useless, middle-aged people, and the same applies to the young. Are they all to be exterminated?

I do not know to what age group Dr. Lund belongs. Obviously not the aged. I hope he has many years of useful work before him. Later in life he will probably look a little more kindly at the old people. So many of them have worked hard and done so much good that they deserve some consideration at the end of life. I trust he will get no support for, or sympathy with, his perfectly horrible suggestion.—I am, etc.,

Hove, Sussex. L. A. PARRY.

SIR,—Dr. J. Rushworth Lund's letter (October 1, p. 758) on the above topic carries with it many dangerous implications which if not refuted may still further damage our society already burdened with the false concept of atheistic materialism. Surely the experience of the last ten years should now indicate to any sensible person how shallow such a concept of life really is.

Has not this materialist concept of life crumbled into dust and ashes in the very sight of those most anxious to build it up?

Old people should never ask themselves, "What use am I in the world?" Nor indeed should anyone. As for sons and daughters unable to marry, has Dr. Lund never heard of charity, the greatest of all the virtues? When a person's natural rights are voluntarily surrendered in the interests of charity that person is living on a very much higher sphere than the person who in similar circumstances insists on the exercise of his natural rights. As to segregation and euthanasia, are these remedies really compatible with the dignity of the individual? Has the individual no supernatural destiny? And who without just cause can take the life of another individual, which, I suggest, Sir, belongs to God and to God alone?—I am, etc.,

Barnsley, Yorks. EDWARD D. JONES.

Paddington Green Children's Hospital

SIR,—I would like to add a word to Dr. D. W. Winnicott's letter (September 24, p. 711). The first post I held in London was as houseman in Paddington Green Children's Hospital fifteen years ago. Since then I have never worked in a more happy hospital nor one in which the individual counted for so much. Everybody knew everybody, from telephone girl to senior physician, and the hospital was a happy, highly efficient unit with a high sense of duty and individual responsibility. It has always seemed to me that this small children's hospital was in its way among the very best of its kind.

In the new order of things it is I suppose inevitable that these things will occur, but is it sufficiently appreciated by the public that they have now one less hospital in their area to serve the local needs, and by the medical profession that it leads to termination of appointments of members of the staff, who have usually given many years' honorary service to such hospitals, without redress and with very little thanks? This mantis-like union of small hospital with large is apparently unhealthy for the patients and medical staff of the smaller partner—the larger, in a few recent instances, digesting bricks and mortar satisfactorily while unable to assimilate the human portion of the diet. In the closing down of Paddington Green Children's Hospital the population of the area has suffered a personal loss, as have also those of us who remember this hospital in the past.—I am, etc.,

London, S.W.1. F. DUDLEY HART.

SIR,—Dr. D. W. Winnicott (September 24, p. 711) has done a great public service in bringing to light the facts concerning the closing of Paddington Green Children's Hospital. It is indeed a tragedy that such an institution, second only to Great Ormond Street in efficiency, can be so quietly planned out of existence. By some mischance St. Mary's was allotted two children's hospitals, whereas there are two other teaching hospitals in the North-West Metropolitan area who have none. It would seem a simple matter to arrange a transfer, and it would save the Ministry of Health £10,000, which is the estimated cost of transforming a 50-bed children's hospital into an adult hospital with half the number of beds. A petition signed by 8,000 mothers, protesting against the closure, has this week been presented to the Minister. Perhaps this plea may prevail where logical argument has failed.—I am, etc.,

London, W.1. MASSEY DAWKINS.

SIR,—Dr. D. W. Winnicott (September 24, p. 711) is to be congratulated on making known the regrettable intention of St. Mary's Hospital Board to close the Paddington Green Children's Hospital and also for stating his views so fairly and so pointedly. Furthermore, I feel absolutely certain his opinions are those of everyone who has had the privilege and joy of serving such a splendid institution and would be strongly supported by countless mothers in the district, and further afield, who have themselves been kindly treated there or regularly take their own children for treatment there in preference to the less personal out-patient department of the general hospitals in the area.

Having been fortunate enough in the course of my paediatric training to have held an appointment at this worthy and happy hospital, I would like to state that Dr. Winnicott's remarks are in no way exaggerated. In fact the personal and happy atmosphere that prevails is one of the outstanding characteristics of the hospital and is quite unique. The decision to close the hospital could only be made by persons ignorant of this fact and of the tremendous amount of work done by the hospital which would have to be diverted to the already crowded, less specialized, and less personal casualty departments of other hospitals.

There can be little doubt that whatever the need for skin or throat beds or whatever the need to adjust St. Mary's undertakings the needs of the mothers and children in the area should be the first consideration. Were this, in fact, the case this decision would never have been contemplated, nor would such an injustice take place. It is only to be hoped that the authorities interested in child health and the treatment of sick children are aware of what is happening and are quick enough and interested and influential enough to prevent this tragic blunder occurring. Renowned as it is, St. Mary's Hospital stands only to lose by this proposal, not only in reputation but by additional strain on its resources. It is to be hoped that those responsible will think again and be prepared to do the just thing.—I am, etc.,

London, W.C.1. RODERICK MAGGS.

What is Social Medicine?

SIR,—I am much obliged to Professor W. Hobson for his very lucid and interesting letter (September 3, p. 546) in reply to my previous letter, and also to Dr. Alice M. Stewart for her courteous letter supporting the views of Professor Hobson. Both writers make it quite clear what they understand by the term social medicine, and no one could gainsay the importance of the work which they envisage, and in which they are engaged. But why call it social medicine? Is not all medicine social, at least in its practical application? And is not social medicine, as explained in these two letters, just preventive medicine writ large? There can only be one purpose animating both—

namely, the promotion of health and the prevention of disease. Social medicine may seek to study and evaluate the conditions, social or otherwise, affecting the incidence of diseases which have not hitherto been investigated on comprehensive lines, and may be able to do so with more efficient means of research than the old public health could afford; but surely this is only a natural extension of the principles of the old preventive medicine, which never set any bounds to its sphere of work.

Public health work in the past sought primarily to provide healthy conditions of life, and by means of health education to secure the intelligent co-operation of the public. Then it made direct attacks on those diseases which appeared most amenable to prevention, e.g., tuberculosis, enteric fever, diphtheria, and venereal diseases, and has done so with a large measure of success. But it did not consider its sphere limited to infectious disease, and by embarking on its schemes for maternity and child welfare, and the school medical service, it entered the realm of general medicine, though mainly from the preventive point of view. Even juvenile delinquency, mentioned by Professor Hobson, has not been overlooked at our child-guidance clinics.

I must confess on re-reading this letter that I may have been engaged on a petty hair-splitting crusade, but I did want to show that the old public health, as it is now called, was not such a hidebound affair as some people seem to think, and that the new public health is not so new as some people try to make out.—I am, etc.,

Torquay. THOMAS GIBSON.

Conceptions of Right and Wrong

SIR,—I can hardly congratulate Dr. J. E. Wilson (September 24, p. 711) on making an allegedly confused opinion of mine on the M'Naghten rules any clearer. With due respect, he seems to have bemused himself with legal terminology and, so far as I can understand his words, manages by a solemn blending of verbal incompatibles to indicate that the answer is in the affirmative and also in the negative.

A simple question was asked in my previous letter about the meaning of the word "wrong" in the M'Naghten rules (used for brevity and convenience—I know about the answers of the judges, etc., which Dr. Wilson brings up). I repeat the question in the plainest way I can think of: (*a*) Does the word "wrong" (as used in the M'Naghten rules) mean wrong according to English law? (*b*) Does it mean morally wrong? (*c*) Is it capable of meaning both according as it suits the purpose of counsel? If Dr. Wilson can cease being awed by the fact that he is dealing with the law and, in equally plain and simple language (preferably in terms of "yes" and "no"), will give me the authoritative answer I am seeking, I shall be in his debt. I might add that I am not in any way abashed by Latin tags.—I am, etc.,

London, W.1. FREDERICK DILLON.

The M.R.C.P.

SIR,—May I draw your attention to the manner in which the Royal College of Physicians introduced the recent changes in the Membership examination? The new regulations were first published at the end of July. The changes which they involved, particularly the new rule forbidding entry to those who have been qualified less than 18 months, were to take effect in the next examination, held at the end of September. However necessary the changes may have been it was surely discourteous of the Royal College to make these sweeping reforms without notice. No university authority would consider a similar change, even in its qualifying examinations, without at least six months' warning being given. The conflicting claims of national service and Membership make it even more difficult for the postgraduate to adjust his plans to such abrupt pronouncements.

To make matters worse, the secretarial staff of the College had no information concerning the details of the 18 months' restriction (i.e., that the period was to be measured from the date of registration to a date one month before the start of the examination) until the week ending September 3. It was possible, therefore, for a candidate who had thought himself just eligible for the September examination to be refused admission less than one month before the date of the first papers. Six months spent in polishing up is largely wasted when a sudden decision of the Royal College puts the examination into the dim period which lies beyond 18 months of military service.—I am, etc.,

HOUSE-PHYSICIAN.

Myxoedematous Madness

SIR,—Dr. E. B. Davies (September 24, p. 706) writes that I inferred that the pattern of psychotic disorder was determined by myxoedema and thinks the title of my paper, "Myxoedematous Madness" (September 10, p. 555), suggests that a specific type of psychosis exists. That is the opposite of what I said—e.g., "Certainly in the series I have observed there has been no constant type of psychosis. . . . It is the disease which is the characteristic feature, not its mental manifestations. . . . There is no specific psychosis." By the title "Myxoedematous Madness" I meant that the myxoedema caused the madness. For instance, the expression "hypoglycaemic reaction" implies that hypoglycaemia causes the reaction, but does not imply that all hypoglycaemic patients behave in a similar way (which they certainly do not).

Dr. Davies suggests that in my cases the myxoedema and the mental symptoms were a coincidence, and considers it misleading to call the association an organic psychosis. It seems fairly obvious the psychoses were organic for several reasons: (1) Because the onset of the psychosis was in every case after the onset of myxoedema. If the association were fortuitous it would be likely for some of the cases to have had psychotic symptoms first. (2) Because the majority recovered dramatically with thyroid. (3) Because in the case that stopped thyroid the mental symptoms returned. (4) Because 50% of cases of myxoedema seen have had psychotic symptoms, whereas 50% of women between 30 and 50 are not psychotic as far as I have noticed. (I have charge of an endocrine clinic and two general medical wards as well as a mental observation ward.)

Dr. Davies's attitude that the search for organic causes for psychoses is as fruitless as the search for the philosopher's stone is not a helpful one. Surely the "gold of psychopathology" is less helpful than malaria in a case of G.P.I. Many organic conditions—cerebral tumour, neurosyphilis, pneumonia, hypoglycaemia, and so forth—undeniably cause psychoses which appropriate treatment usually cures. I never wrote (as Dr. Davies seems to think) that "all the common psychoses . . . are determined by organic causes." I suggested that *some* might be found to be so caused. The majority of psychoses remain of unknown or psychopathological origin, but where physical causes exist their detection is a rewarding task for either physician or psychiatrist.—I am, etc.,

London, N.W.10. RICHARD ASHER.

POINTS FROM LETTERS

Distinction Awards

Dr. A. B. STEWART (Bury, Lancs) writes: Patients have already decided which family doctor will help them most and have awarded him their capitation fees. There is no chance of distinction awards for G.P.s. In my opinion the primary duty of the consultant is to help, in every sense of the word, the family doctor and through him the patient. If this opinion is accepted it follows that the G.P. should decide which consultants have given most assistance and thus qualify for distinction awards. Logically this process for deciding distinction awards can be carried a further stage. Consultants whose distinction awards are decided by G P.s should in turn decide which of their colleagues outside the orbit of G.P.s are rendering most help in the assistance given to family doctors and their patients, thus qualifying for distinction awards. Thus the sequence of reward and responsibility, from patient to remotest research worker, could be made complete.

Medical Notes in Parliament

Imported Books

During the special sittings of Parliament Mr. HAROLD WILSON made a statement on September 29 in the House of Commons about the relaxation of import restrictions. He announced the issue, as from October 5, of open general licences which would permit anyone to import the goods concerned without an import licence from any country other than those specifically excluded. He circulated a list of goods to be included on open general licences, which specified chemicals, drugs, and medicines, with various medical, surgical, and dental appliances and instruments. Books were also on the list; and from October 5 an open general licence would be issued for all imports of books from "soft currency" countries. Countries excepted from the scope of open general licences include the United States, Canada, countries in Central and South America, Belgium, Switzerland, Western Germany, the U.S.S.R., and European countries associated with it. On September 27 Mr. M. C. HOLLIS had raised the question of the licensing of the import of books. He said that as a result of this licensing the country's educational life had suffered. Frequently pupils had been told to read for examinations books which were not obtainable in this country. Scientific work had been hampered. Since by the loan agreement Britain must not discriminate against the Americans, it must exclude all works from every country so that the Americans did not have a grievance. If they could not have unlicensed import of books from the United States of America, at least they should have a free import of books from Europe, Eire, and the Dominions.

Mr. KENNETH LINDSAY said almost every country represented at the Strasbourg Assembly had similar quotas and restrictions to Great Britain. European unity should be made a reality at least in the world of books.

Mr. A. G. BOTTOMLEY, replying for the Government, said that as a result of the Anglo-American Loan Agreement they could not allow books to come into this country which they prohibited from the United States. Learned scientific and technical books were allowed in at the rate of 200% by value of pre-war imports. Import licences were issued quarterly, and the Government was arranging that for the next quarter the same ratio as before would come in. In addition, by the open general licence scheme any student who required a certain book could get it, although in some cases delay was unavoidable. The import of books from the United States must be limited. The Government could not consider taking anything further from the United States.

Medico-Legal

DRUGS LEFT IN CAR

A doctor was recently fined £10 for keeping dangerous drugs other than in a locked receptacle.[1] He had pleaded guilty. The prosecution contended[2] that the doctor's case had been found with some of its contents strewn on the ground. The case was taken to the police and was found to be unlocked. There was no sign of the lock having been tampered with. Among the contents missing were some tablets of pethidine and some morphine preparations.

The defence said that all the drugs were recovered immediately and no harm had been caused to anybody. The only person who could report the loss of dangerous drugs from a doctor's car was the doctor himself. If doctors were to be rewarded for reporting their loss to the police by being prosecuted, they would be discouraged from reporting it. The magistrate said that a serious case had been aggravated by the doctor leaving the unsecured drug case in his unlocked car.

*With honours. †With commendation

UNIVERSITY OF LONDON

A course of three lectures on "The Chemistry of the Transuranics and Other Newly Discovered Elements" will be given by Professor H. J. Emeléus, F.R.S., at the University College (Chemistry Theatre), Gower Street, London, W.C., on Mondays, October 31, November 7 and 14, at 5.15 p.m.

Mr. A. J. Wright, Director of Medical Postgraduate Studies in the University of Bristol, will deliver the Semon Lecture on "Tonsillar Function: A Review of the Evidence" at the Royal Society of Medicine, 1, Wimpole Street, London, W., on Thursday, November 3, at 5 p.m.

Professor J. Z. Young will deliver two lectures on "The Structure of Peripheral Nerve" at University College, Gower Street, London, W.C., on Mondays, October 10 and 17, at 5.15 p.m.

A course of three lectures on "Growth and Reproduction of Bacteria" will be delivered by Sir Paul Fildes, F.R.S., in the Anatomy Theatre of University College, Gower Street, W.C., on October 19, 20, and 21, at 5.30 p.m.

Sir James Learmonth, Professor of Surgery and Clinical Surgery in the University of Edinburgh, will deliver a course of four Heath Clark Lectures at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, W.C., on November 21, 22, 23, and 24, at 6 p.m. His subject is "The Contribution of Surgery to Preventive Medicine."

All the above lectures are addressed to students of the University and to others interested in the subjects. Admission is free, without ticket.

UNIVERSITY OF WALES

The Council of the Welsh National School of Medicine has appointed Frederick Roland George Heaf to the David Davies Professorship of Tuberculosis at the school.

Dr. Heaf qualified at St. Thomas's Hospital in 1918, taking the Cambridge degree two years later. He proceeded M.D. in 1923 and was elected F.R.C.P. in 1946, having taken the Membership in 1941. Dr. Heaf is Senior Medical Officer, London County Council, Adviser in Tuberculosis to the Ministry of Health, and president of the British Tuberculosis Association.

UNIVERSITY OF LIVERPOOL

The following candidates have been approved at the examination indicated:

FINAL M.B., Ch.B.—*Part I:* Hilary A. Hagan, J. A. Howe, W. R. Howell, H. G. McDonald, Angela M. M. Manning, T. W. Merrick, J. B. Newton, E. Patrick, J. W. Prout, Megan Roberts, D. Winter.

UNIVERSITY OF SHEFFIELD

The following candidates have been approved at the examinations indicated:

M.D.—Helen N. Mellanby, E. L. M. Millar.

FINAL M.B., Ch.B.—Daphne Burkinshaw, Nancy Cole, J. D. Crabtree, P. Kelly, Barbara Kilpatrick, P. O. M. McGirr, S. Mohamedi, F. L. Myers, G. H. Pagdin, Kathleen Sampson.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended September 17. [No. 37

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1949 (a)	(b)	(c)	(d)	(e)	1948 (Corresponding Week) (a)	(b)	(c)	(d)	(e)

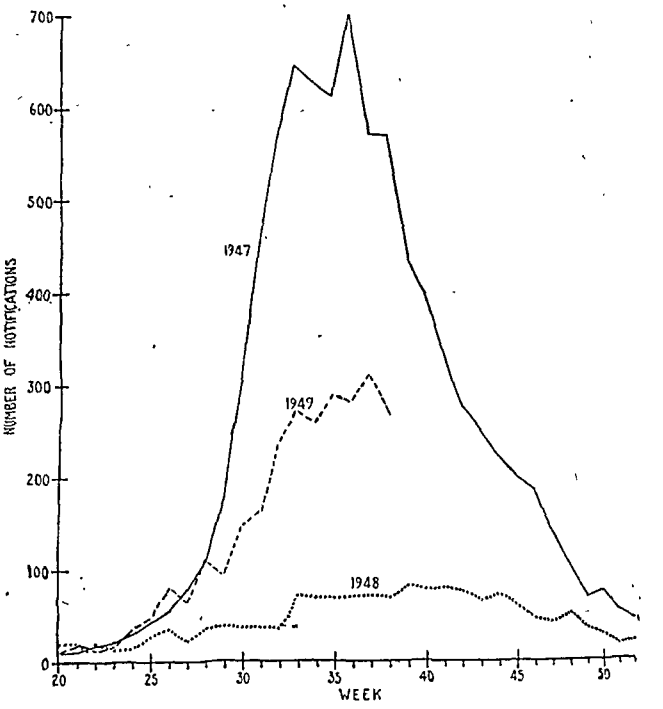
* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.



§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

‖ Includes puerperal fever for England and Wales and Eire.

EPIDEMIOLOGICAL NOTES

Poliomyelitis

Notifications in England and Wales for the week ended September 24 were: poliomyelitis 268 (311), polio-encephalitis 27 (31). The figures for the previous week are shown in parentheses. This is the first substantial fall since the rise in notifications began in the twenty-fourth week of this year. The curve generally has followed that of 1947 fairly closely, and it is to

be hoped that the decline which began in the thirty-seventh week of that year has now set in. For comparison the curves for the present year and for 1948 and 1947 are set out in the accompanying graph.

Multiple cases (poliomyelitis and polio-encephalitis together) were reported from the following counties: London 48 (41), Berkshire 3 (7), Cheshire 7 (4), Cornwall 8 (10), Devon 5 (5), Dorset 4 (3), Essex 17 (18), Hertford 7 (4), Kent 18 (16), Lancaster 24 (29), Leicester 5 (13), Lincolnshire, Holland 4 (1), Lincolnshire, Lindsey 4 (6), Middlesex 20 (25), Norfolk 2 (3), Northampton 4 (3), Northumberland 13 (10), Nottingham 9 (11), Oxford 3 (0), Soke of Peterborough 2 (1), Somerset 7 (8), Southampton 8 (10), Suffolk East 5 (1), Surrey 11 (14), Sussex West 2 (1), Warwick 8 (10), Westmorland 2 (0), Wiltshire 9 (6), Yorks West Riding 19 (33), Glamorgan 3 (3).

In the United States a peak of incidence was reached with 3,419 cases of poliomyelitis in the week ended August 20, and since then the notifications have been fewer. Already 29,051 cases have been reported this year.

Sex and Age Composition of Population

Estimates compiled by the Registrar-General of the civilian populations of each local government area in England and Wales, showing the numbers of each sex at various age groups, have recently been published.[1] Figures such as these are usually only available when a census is taken. Owing to the war, there has been no census since 1931, and the latest figures previously available were those based on the enumeration carried out for national registration purposes on September 29, 1939. Those figures were affected by mobilization and evacuation and could not be regarded as reflecting normal conditions.

The present figures relate to December 31, 1947, and have been largely based on a special examination of the individual

[1] *Estimates of the Sex and Age Distribution of the Civilian Population in Regions and Administrative Areas of England and Wales at December 31, 1947.* H.M.S.O., price 2s. 6d.

population records maintained in the local National Registration Offices through the country. In most areas there are wide differences between the numbers of men and numbers of women at certain age groups, which are mainly due to the exclusion of members of the armed Forces and merchant seamen from the figures. For the country as a whole the approximate ratios of males to every 1,000 females (*including* members of the armed Forces and merchant seamen) at the age groups mainly affected are as follows:

All ages	940	25–34	986
18–19	1,017	35–44	992
20–24	1,021	45–54	988

Comparing the 1947 figures with those obtained from the 1931 census, the general ageing of the population is readily apparent. For instance, during this 16-year period (*a*) the proportion of the total population of England and Wales under 15 years of age has fallen from 23.8% to 21.9%, and the proportion over 65 has risen from 7.4% to 10.9%; (*b*) corresponding figures for Wales alone are: under 15, a fall from 26.6% to 22.4%; over 65, a rise from 6.7% to 10.8%; (*c*) for the administrative county of London the figures are: under 15, a fall from 21.5% to 18.9%; over 65, a rise from 7.3% to 10.8%.

Discussion of Table

In *England and Wales* there were increases in the notifications of scarlet fever 213, acute poliomyelitis 27, dysentery 27, and diphtheria 12, with decreases in the incidence of measles 187 and whooping-cough 48

An increased incidence of scarlet fever was reported throughout the country. The rise in the incidence of diphtheria was due to scattered isolated cases; the largest returns during the week were London 10, Durham 10, and Lancashire 9. The largest returns for measles came from Lancashire 106, Durham 72, London 42, and Yorkshire West Riding 38. The largest fluctuation in the incidence of whooping-cough was an increase of 31 in Middlesex.

Outbreaks of dysentery were notified in Durham, Hetton U.D. 15; Glamorganshire, Neath M.B. 11; Yorkshire West Riding, Dewsbury C.B. 8; and Essex, Thurrock U.D. 6. The incidence of food-poisoning was high in Essex 86, London 40, and Norfolk 28.

In *Scotland* there were decreases in the notifications of dysentery 38 and acute primary pneumonia 24, while increases were reported for cerebrospinal fever 13, whooping-cough 13, and diphtheria 9. The rise in the incidence of cerebrospinal fever and diphtheria was mainly contributed by Glasgow. Of the 54 cases of dysentery 45 were notified in Glasgow. Cases of paratyphoid fever were notified from Lanark County 3 and Glasgow 2.

In *Eire* there were falls in the notifications of whooping-cough 54 and scarlet fever 26, with a rise in the incidence of measles 26. Notifications of diarrhoea and enteritis were 3 more than in the preceding week, but in Dublin C.B. the notifications fell from 115 to 105. The decrease in the incidence of whooping-cough and scarlet fever was due to the experience of Dublin C.B. A small rise in the incidence of measles was recorded throughout the country.

In *Northern Ireland* the chief fluctuations were a rise of 27 in the notifications of scarlet fever and a decrease of 26 in the notifications of whooping-cough.

Week Ending September 24

Notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,097, whooping-cough 1,061, diphtheria 92, measles 659, acute pneumonia 226, cerebrospinal fever 35, acute poliomyelitis 268, acute polio-encephalitis 27, dysentery 78, paratyphoid fever 23, typhoid fever 8, food-poisoning 245.

The Ministry of Food states that minute traces of lead in curry powder and copper in tomato products are not uncommonly found. Maximum limits for these elements have therefore been prescribed, and the composition of these and other commodities defined, by the Food Standards (Curry Powder) Order, 1949, and the Food Standards (Tomato Ketchup) Order, 1949, under the Defence (Sale of Food) Regulations.

Medical News

Hospital to Reopen

The South-Eastern Hospital for infectious diseases at New Cross, London, S.E., is to be reopened as the New Cross General Hospital, with accommodation for about 200 patients.

"Academician Pavlov"

As part of the Pavlov centenary celebrations the film "Academician Pavlov" was shown to an invited audience on September 26. The film, which runs for over an hour, was well received.

Jodrell Chair of Physiology

Professor C. Lovatt Evans, F.R.S., has retired from the Jodrell Chair of Physiology of London University, and was succeeded from October 1 by Professor George Lindor Brown, F.R.S., whose appointment has been announced previously

Streptomycin Manufacture Controlled

From October 1 streptomycin can be manufactured for sale only under licence, and it must conform with prescribed conditions as to strength, quality, and purity. These requirements are laid down in the Therapeutic Substances Amendment Regulations, 1949.

Import Restrictions Relaxed

The Board of Trade has announced that restrictions have been relaxed on the import of drugs and other chemicals, medical and surgical instruments, and books obtained from countries where they can be bought without risk of losing gold or dollars.

Prize for Work on Thyroid

The American Goiter Association offers the Van Meter prize of 300 dollars and two honourable mentions for the best essays submitted on original work related to the thyroid gland. The essays may be on either clinical investigation or research, and should not be longer than 3,000 words. Two copies should be sent to the corresponding secretary, Dr. George C. Shivers, 100, East St. Vrain Street, Colorado Springs, Colorado, U.S.A., before January 15, 1950.

Colour Television

A demonstration of colour television, with equipment suitable for viewing surgical operations, was given by Messrs. Pye, Ltd., at Olympia on October 3. A number of articles were shown being televised—some, brightly coloured, such as a bowl of flowers, and others, such as human bones, less colourful. The equipment operates at 405 lines a frame, and gives the same definition as the B.B.C. transmissions. The colours are effectively natural, though comparison with the objects being televised showed that they departed considerably from their actual colours. There was no flare from the highly polished surgical instruments, and the depth of focus allowed the furthest parts of a mandible to be seen as clearly as the nearest when it filled the screen. The apparatus seems to be entirely suitable for televising operations, and probably an audience of 20 or 30 would have a good view of the surgical field. At present the approximate cost of the equipment is £25,000.

Wills

Dr. John Wardle Bone, formerly Treasurer of the B.M.A., left £73,952; Dr. Joseph Henry Churchill, of Bath, left £12,369; Dr. Charles Cromhall Easterbrook, of Edinburgh, £48,949; Dr. Wilfred Nightingale, of Lytham St. Annes, £13,131; Dr. John Finlayson Lang, of Rathgate, West Lothian, £12,560.

COMING EVENTS

Royal Eye Hospital Lectures

A series of lectures at the Royal Eye Hospital, St. George's Circus, London, S.E., opened on October 3 and will be continued during this month and in November and December, and January, 1950. The lectures are open to both postgraduate and undergraduate students. Details of fees and subjects may be obtained from the secretary of the hospital.

Nurses' Conference

The eighth conference on the nation's nurses, arranged by the Royal College of Nursing (Henrietta Place, Cavendish Square, London, W.), will be held at the College to-day and to-morrow (Friday and Saturday, October 7 and 8) at 10 a.m. The subject for discussion on October 7 is "The Industrial Nursing Service and the Worker," and that on October 8 "Economy in Nurse Power." The conference fee is £1 1s.

Royal College of Obstetricians and Gynaecologists

The annual dinner of the Royal College of Obstetricians and Gynaecologists will be held at Dorchester Hotel, Park Lane, London, W., on Wednesday, October 12, at 7 for 7.30 p.m.

Adlerian Society of G.B.

The first meeting of the medical section of the Adlerian Society of Great Britain will be held at 11, Chandos Street, Cavendish Square, London, W., on Thursday, October 13, at 8 p.m. Papers will be read by Drs. Neville Murray and Joshua Bierer on "Prolonged Sneezing as a Psychosomatic Symptom." The discussion will be opened by Mr. E. O. Harris and Drs. C. J. C. Britton and H. Fleetwood Walker. All medical practitioners interested are invited, and further information may be obtained from Dr. Christine E. Cooper, honorary secretary of the medical section, 115 Langford Court, London, N.W.8.

Nurses and Midwives Conference

The 34th annual Professional Nurses and Midwives Conference will be held, under the auspices of the *Nursing Mirror*, at Seymour Hall, Seymour Place, London, W., from October 17 to 21, under the presidency of Viscount Addison. The programme is as follows: October 17, 11 a.m., opening address; 11.45 a.m., Dr. C. T. Porter, "Neonatal Period and Its Disorders"; 2.45 p.m., Sir William Gilliatt, "Changes in the Practice of Obstetrics"; 4.45 p.m., Mr. H. G. E. Arthure, "The Management of the Puerperium." October 18, 10.15 a.m., Professor A. M. Boyd, "Some Recent Advances in Surgery of the Blood Vessels"; 11.30 a.m., Mr. T. Holmes Sellors, "The Blue Baby—Operation for Congenital Heart Disease"; 2.15 p.m., Mr. D. W. C. Northfield, "Sympathectomy"; 3.30 p.m., Mr. G. A. Mason, "Surgical Treatment of Coronary Thrombosis"; 4.45 p.m., Mr. Wylie McKissock, "Operations for Changing the Mental State." October 19, 10.15 a.m., Dr. Terence E. Cawthorne, "Ménière's Disease"; 11.30 a.m., Dr. C. F. Terence East, "Hypertension"; 2.15 p.m., Dr. H. S. Le Marquand, "Endocrine Disorders of Childhood"; 3.30 p.m., Dr. J. B. Murray, "Psychosomatic Medicine"; 4.45 p.m., Mr. R. W. Knowlton, "Diagnosis and Treatment of Non-venereal Vaginal Discharges." October 20, 10.15 a.m., Mr. George Wynn-Williams, "Hyperemesis Gravidarum"; 11.30 a.m., Mr. Arthur C. H. Bell, "Albuminuria of Pregnancy"; 2.15 p.m., Mrs. Fox, "Relaxation in Childbirth"; 3.30 p.m., Mr. F. W. Roques, "Displacement of the Uterus"; 4.45 p.m., Professor R. J. Kellar, "Rupture of the Uterus." October 21, 10.15 a.m., Dr. Alfred Piney, "Bone Marrow Biopsy"; 11.15 a.m., Professor J. S. Mitchell, "Radioactive Isotopes"; 12.15 p.m., Dr. F. C. C. Valentine, "Streptomycin and the Newer Antibiotics"; 2.30 p.m., Mr. Leon Gillis, "Recent Progress in the Treatment of Arm Amputations and Arm Prostheses." Throughout the week there will be twice-daily sessions of the latest medical films, and in the exhibition hall there will be a display of drugs, foods, pharmaceuticals, and equipment. Admission to the conference and exhibition is limited to professional visitors. Applications for tickets should be made to matrons of hospitals and similar institutions, to nursing associations, to the Royal College of Midwives, or to the organizer of the conference, Dorset House, Stamford Street, London, S.E.1.

Osler Club

The next meeting of the Osler Club will take place on Friday, October 21, at 8 p.m., in the Wellcome Historical Medical Library, 183, Euston Road, London, N.W.1. The speakers will be Mr. W. R. LeFanu, librarian of the Royal College of Surgeons, on "Edward Jenner, Author and Letter Writer," and Professor G. S. Wilson, of the Ministry of Health Public Health Laboratories, whose subject will be "Smallpox and After." There will also be an exhibition of books and papers related to Edward Jenner and his work.

American Public Health Association

The 77th annual meeting of the American Public Health Association will be held in New York on October 24–28.

27 General Hospital

A reunion dinner of No. 27 General Hospital will be held at the Eccleston Hotel, Eccleston Square, London, S.W.1, on Saturday, October 29, at 6.30 for 7.15 p.m. (dress informal). Remittances of 15s. 6d. (inclusive) should be sent to Mr. G. L. Pudney, 161, Silverleigh Road, Thornton Heath, Surrey.

Brigade Surgeons' Conference and Dinner

The surgeons of the St. John Ambulance Brigade will hold their annual conference and dinner at the Waldorf Hotel, Aldwych, London, W.C., on Saturday and Sunday, October 29 and 30, when Lord Horder will be the principal guest at the dinner. At the conference there will be talks on the effects of atomic warfare and the treatment of casualties; on shock, its effects and treatment; and on the use of films in teaching. Further details can be obtained from the Surgeon-in-Chief, St. John Ambulance Brigade, 8, Grosvenor Crescent, London, S.W.1.

Royal Institute of Philosophy

The programme for the 1949–50 session of the Royal Institute of Philosophy includes lectures to be given at University Hall, 14, Gordon Square, London, W.C., and evening meetings to be held at University College (Anatomy Theatre), Gower Street, London, W.C., during this month and in November and January, February, and March, all of which are open to the public. Cards of admission may be obtained free of charge from the director of studies of the Institute at 14, Gordon Square, W.C.1. Details will be published under "Societies and Lectures" in the *Journal* week by week.

Canadian Course in Cytology

A course in clinical cytology for the diagnosis of uterine and other types of cancer will be held at McGill University, Montreal, under Dr. J. Ernest Ayre, on November 7–21, at the Cytological Laboratories, Royal Victoria Hospital, Montreal. The fee for tuition is $100.

Courses in Psychiatry

The University of London Institute of Psychiatry will hold courses for first-year and second-year students on psychology and psychiatry this autumn. The fee for one term's lectures is 12 guineas, and for separate series of lectures proportionate fees will be charged. Particulars may be obtained from the dean, Institute of Psychiatry, Maudsley Hospital, Denmark Hill, London, S.E.5 (Telephone: Rodney 2634).

SOCIETIES AND LECTURES

Friday

NATIONAL HOSPITAL, Queen Square, London, W.C.—October 7, 5 p.m., "*Observations on the Anatomy of Memory*," by Dr. Wilder Penfield (Montreal).

Monday

LONDON UNIVERSITY.—At University College, Gower Street, London, W.C., October 10, 5.15 p.m., "*The Structure of Peripheral Nerve*," by Professor J. Z. Young.

MEDICAL SOCIETY OF LONDON, 11, Chandos Street, Cavendish Square, London, W.—October 10, 8.30 p.m., General meeting; 8.45 p.m., "*The Sigmoidoscope*," Presidential Address by Mr. Lionel E. C. Norbury.

NATIONAL HOSPITAL, Queen Square, London, W.C.—October 10, 5 p.m., "*Allergic Manifestations in the Nervous System*," by Dr. Foster Kennedy (New York).

Tuesday

INSTITUTE OF DERMATOLOGY, 5, Lisle Street, Leicester Square, London, W.C.—October 11, 5 p.m., "*Histology of the Skin*," by Dr. I. Muende.

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Postgraduate Medical School of London, Ducane Road, W., October 11, 3 p.m., "*Problems of Infertility in a County Centre*," by Dr. Margaret Jackson.

SOCIETY OF CHEMICAL INDUSTRY: FINE CHEMICALS GROUP.—At Royal Institution, Albemarle Street, London, W., October 11, 7 p.m., "*Biological Polymerization with Special Reference to Polysaccharide Synthesis*," by Professor M. Stacey, Ph.D., D.Sc.

Wednesday

GLASGOW UNIVERSITY: DEPARTMENT OF OPHTHALMOLOGY.—October 12, 8 p.m., "*Control of Clotting in Ophthalmology*," by Dr. W. O. G. Taylor.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS, 58, Queen Anne Street, London, W.—October 12, 2.30 p.m., "*Scotland's Contribution to the Progress of Midwifery in the Eighteenth and Early Nineteenth Centuries*," William Meredith Fletcher Shaw Memorial Lecture by Professor R. W. Johnstone.

SOCIETY OF CHEMICAL INDUSTRY: FOOD GROUP.—At Medical Society of London, 11, Chandos Street, Cavendish Square, London, W, October 12, 6.15 p.m., meeting of Microbiological Panel. "*Aspects of the Mineral Metabolism of Micro-organisms*" (1) *Use of Aspergillus niger for the Determination of Mineral Nutrients in Soil*, by Dr. D. J. D. Nicholas; (2) *Effect of Ion Exchange Treatment on (a) Composition, (b) Microbiological Stability of Apple Juice*, by Drs. D. W. Challinor and A. Pollard.

YORK MEDICAL SOCIETY.—At Tempest Anderson Hall, York, October 12, 3 p.m., "*New Pathways in Medicine*," by Sir Henry Cohen.

Thursday

INSTITUTE OF DERMATOLOGY, 5, Lisle Street, Leicester Square, London, W.C.—October 13, 5 p.m., "*Skin Affections of the Hands and Feet*," by Dr. G. B. Mitchell-Heggs.

NATIONAL HOSPITAL, Queen Square, London, W.C.—October 13, 5 p.m., "*Diagnostic Errors in Neurological Practice*," by Professor G. H. Monrad-Krohn (Oslo).

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Corner, London, S.W.—October 13, 4.30 p.m., lecture-demonstration: "*Psychiatry*," by Dr. D. Curran.

WESTMINSTER HOSPITAL SCHOOL OF MEDICINE, Meyerstein Lecture Theatre, Horseferry Road, London, S.W.—October 13, 5.30 p.m., Clinico-pathological demonstration. Discussion: "*Leukaemia and its Treatment*."

Friday

ROYAL INSTITUTE OF PHILOSOPHY, 14, Gordon Square, London, W.C.—October 14, 5.15 p.m., "*Scope and Aims of 'Synoptic' Philosophy*," by Professor H. H. Price.

ROYAL SANITARY INSTITUTE.—At Tunbridge Wells Town Hall, October 14, 10 a.m., "*Newer Methods in the Tracing of Typhoid Outbreaks Including the Value of Phage Typing*," discussion to be opened by Professor J. C. Cruickshank.

Saturday

NORTH OF ENGLAND OTOLARYNGOLOGICAL SOCIETY.—At Harrogate and District General Hospital, Knaresborough Road, Harrogate, October 15, 2 p.m., Annual Meeting.

NUTRITION SOCIETY.—At Department of Pharmacology, Birmingham University, October 15, 1.15 p.m., "*Triglyceride Fats in Human Nutrition*," by Professor A. C. Frazer, Drs. J. Elkes and J. M. French (Department of Pharmacology, Birmingham University), Professor T. P. Hilditch (Department of Industrial Chemistry, Liverpool University), and Professor P. Kraut (Berlin).

YORK MEDICAL SOCIETY.—At 17, Stonegate, York, October 15, 8.30 p.m., "*Diagnosis and Prevention of Whooping-cough*," by Professor Robert Cruickshank.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Cole.—On September 17, 1949, at City and County Hospital, Londonderry, to Nancy (née Jones), S.R.N., wife of J. O. Y. Cole, M.D., D.M.R.E., a son—David Owen James.

Hargrove.—On September 23, 1949, at the Hill Nursing Home, Reading, to Elizabeth (née Corbett-Lowe), wife of Dr. Peter Hargrove, a daughter—Gillian Dingwall.

Hopwood.—On September 20, 1949, at Kampala, Uganda, to Shirley (née Newman), wife of Dr. B. E. C. Hopwood, a brother for Penelope Ann—John Burton.

Lewes.—On September 24, 1949, at The Haven, Great Chesterford, to Daphne (née Wailes) and David Lewes, M.R.C.P., a daughter—Jane Christina.

Ronchetti.—On September 18, 1949, at Winchmore Hill, to Sylvia (née Helme), wife of Dr. John Ronchetti, a sister for John Kirkland.

MARRIAGES

Brearley—Hewitt.—On September 8, 1949, at Sandiway, Cheshire, Roger Brearley, M.B., F.R.C.S., to Joyce Mary Hewitt.

Webber—Hay.—On September 28, 1949, at St. Peter's Church, March, Cambs, George Edward Francis Webber (formerly of Buenos Aires and India) to Hilda Russell Hay, M.B., Ch.B., D.P.H., County Medical Officer, Isle of Ely.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Streptomycin during Pregnancy

Q.—*Is there any evidence that administration of streptomycin during pregnancy is likely to result in labyrinthine damage to the foetus?*

A.—The answer to this question is probably not yet known, because comparatively few women have received streptomycin during pregnancy. Moreover, streptomycin has been available for only a short time, and it will presumably be necessary to wait until children exposed to its influence *in utero* are 1½ to 2 years old before their auditory function can be assessed with any degree of certainty. Streptomycin can cross the placenta, and has been demonstrated in the foetal blood in amounts comparable to those in the maternal circulation, and also in liquor amnii in heavy concentration; toxic effects might therefore be expected. On the other hand, there is some evidence that damage to the auditory apparatus is a less common side-effect in children than in adults.

This problem would appear to be of considerable importance, and it is to be hoped that those who have experience of administering streptomycin to pregnant women will comment on the results to the foetus, if possible relating them to the period of pregnancy at which treatment was given.

Temperature and Pulse Rate in Phthisis

Q.—*Above what levels of oral temperature and resting pulse rate is activity indicated in a patient with pulmonary tuberculosis (a) when resting in bed and (b) when getting up?*

A.—The variations which can occur in the so-called normal temperature in health are greater than is generally realized. A diurnal variation of 3° F. (1.6° C.) is common, and the temperature range is at different levels in different individuals. Thus, one healthy subject may have a daily variation between 97.2° and 99.2° F. (36.2° and 37.3° C.), while another's may be between 95° and 98° F. (35° and 36.7° C.). These facts, which have been fully described recently by Samson Wright (*Journal*, April 9, 1949, p. 610), are of great importance when evaluating the temperature of a tuberculous patient. It is necessary first to estimate the normal range for the particular individual, since a rise to 99° F. (37.2° C.) in a patient with a high normal range may be of no significance, whereas it may indicate fever in a patient with a low normal range. In general, it may be said that a reading above 99.5° F. (37.5° C.) in a patient who is resting in bed probably indicates disease activity. The temperature must be taken at the same times each day, and these should not be after meals: the thermometer must always remain in the mouth for a full five minutes to obtain an accurate reading. Allowance must be made for the considerable variations in temperature which accompany the menstrual cycle in most women. Occasionally a patient who has been in bed for some time will have an evening temperature of about 100° F. (37.8° C.), and this will come down to a lower level when the patient starts to get up. Such a "bed temperature" is by no means uncommon. When the patient is up and about, other factors, such as variations in external temperature and muscular exercise, will alter the temperature range. A rise in temperature of 1° F. (0.55° C.) after exercise is not uncommon, but this should settle down after half an hour's rest.

The pulse rate is a less reliable guide. Usually it follows the temperature, but it is much more easily affected by nervousness. A persistent tachycardia should lead one to suspect activity of the disease; wide variations in the pulse rate are probably due to psychological causes. It must be stressed that both temperature and pulse rate are far inferior to serial radiography in assessing the progress of a case of pulmonary tuberculosis. *X* rays not infrequently reveal active disease in a patient who is afebrile.

Urethritis

Q.—(*a*) *What are the signs and symptoms of urethritis in the male due to Trichomonas vaginalis, and what treatment is indicated?* (*b*) *Are there any cases on record of urethritis caused by spermicidal contraceptives?*

A.—(*a*) The signs and symptoms of urethritis in the male due to *Trichomonas vaginalis* do not differ in any important respect from those due to various other forms of non-gonococcal urethritis, but it is probable that *T. vaginalis* more often causes a balanoposthitis or prostatitis than a simple urethritis. Rendering the urine alkaline is said to be effective in most cases, but a more reliable form of treatment consists in filling the urethra with powdered acetarsol in water or saline, holding it there for a few minutes, and milking it back as far as possible towards the posterior urethra.

(*b*) Most venereologists consider that various contraceptive chemicals are liable to cause urethritis, but it is obviously difficult to prove that they do so.

Intravenous or Intramuscular Heparin

Q.—*Disregarding speed of action, is heparin less efficacious when given intramuscularly than when given intravenously?*

A.—Heparin, being expensive, is usually given intravenously, but it is just as efficient when given intramuscularly, provided the dose is at least doubled—some say trebled or quadrupled. The precise comparable dose is still uncertain.

Rheumatoid Arthritis and Epilepsy

Q.—*Are any statistics available showing the coincidence of rheumatoid arthritis and epilepsy? In a small experience I have not encountered such a combination. If the coincidence of the two diseases is rare, might the recent discovery of "cortisone" be a pointer to the aetiology of epilepsy?*

A.—There appear to be no statistics showing the coincidence of rheumatoid arthritis and epilepsy, nor is the occurrence of rheumatoid arthritis recorded as being more or less frequent in epileptics than in the normal population. It would seem a somewhat far-fetched assumption, on the basis of these negative observations, that there may be a common aetiological factor. It is known, however, that "cortisone" (17-hydroxy-11-dehydrocorticosterone; compound E) will produce a well-marked euphoria in arthritics and others, and this fact has led certain psychiatrists to assume that it may perhaps prove of some value in nervous and psychiatric illness.

Effect of Pregnancy on Libido

Q.—*Is there any explanation for the fact that after their first pregnancy many young women experience a loss of sexual appetite and satisfaction? There has been no active distaste in two cases seen recently—merely an indifference where before there had been desire. Both are healthy young women with second children, and no physical cause can be found. Is the condition likely to ameliorate—one case is of three years' duration, the other of 18 months? Is there any treatment?*

A.—Reduced sex desire after pregnancy, especially the first pregnancy, is the experience of most women. The fact that a fundamental objective of coitus has been achieved, the awakening of mother love with some readjustment of the woman's affections, the extra work and anxiety associated with looking after the child, etc., all play their part. A local organic basis is most unlikely so far as sex desire is concerned, although an overstretched vagina might diminish satisfaction. These troubles, however, are usually only temporary and clear up as the period of nervous strain passes, as physical well-being returns, and as the baby grows independent. If loss of libido should persist, another factor—fear of pregnancy—should be kept in mind, and in such a case the appropriate treatment is advice on contraception. Explanation and reassurance may be all that is necessary in other cases. The wife should avoid getting overtired, and the husband should have patience and understanding.

NOTES AND COMMENTS

Toxic Effects of "Diparcol."—Dr. R. C. MEEK (Birmingham) writes: In "Any Questions?" in a recent issue of the *Journal* (August 13, p. 398) an inquiry was made by a reader regarding the dangers of the drug "diparcol." In the reply it is stated that French workers reported a fatal case of agranulocytosis but considered this to be due to other drugs used at the same time. In view of the present extensive use of diparcol I think the following experience may be of interest. The patient, a married woman aged 58, had suffered from post-encephalitic parkinsonism since about 1935. On admission to hospital on May 18, 1949, she showed extreme rigidity of the face, neck, trunk, and all four limbs, and a rhythmic tremor of the hands. Diparcol was started on May 29, 1949, in a dosage of 50 mg. b.d. The dosage was steadily increased till July 15, 1949, by which date she was receiving 1 g. daily. On this dosage there was considerable relief of the rigidity and tremor. She was kept on 1 g. daily till July 28, 1949, when slight mental confusion developed; the dosage was reduced to 400 mg. daily. On August 4, while still on 400 mg. daily, she complained of a sore throat and general malaise. Examination showed a temperature of 99.5° F. (37.5° C.), a patch of exudate on one tonsil, and a few small boils on the trunk. Diparcol, which was the only drug she was receiving, was stopped and she was put on penicillin 50,000 units 3-hourly. A white cell count showed a total of 3,900 per c.mm. with only 4% granular cells; a throat swab showed a heavy mixed growth with a coagulase-positive staphylococcus predominating. On August 5, 1949, in spite of treatment (which by this time included pentose nucleotide) the temperature had risen to 103° F. (39.4° C.), and she now showed large patches of exudate covering both tonsils. She died on August 6, 1949. At necropsy it was seen that there were ulcers on the posterior part of the tongue in addition to those on the tonsils. The lungs were oedematous, and there was congestion of the bronchial mucosa but no evidence of bronchopneumonia. The liver showed cloudy swelling and the spleen was large and soft. The bone marrow was not grossly abnormal macroscopically. The microscopic appearance of the bone marrow was summed up by the pathologist: "The appearance is that of diminished formation or destruction of early forms of the granulocyte series."

Medical Treatment of Myopia.—Mr. A. SEYMOUR PHILPS (London, W.) writes: I was surprised to read under "Any Questions?" (August 13, p. 398) the statement that medical treatment of myopia, such as the administration of calcium, is not now much used, and that in these days chief reliance is placed on ordering a full correction at as early an age as possible, and that the glasses should be worn all day long. I should have thought that this was the exact opposite of the facts. Glasses are pieces of glass which help the eyes to focus, and they are given to the child in order that he or she may see what is going on and derive some benefit from education. I thought it was commonly agreed that they had no influence whatever on checking myopia, and certainly it is true that myopes do not become worse by leaving them off. While proof is difficult, it does seem that attention to general health, feeding, conditions of work, and the possible administration of calcium and vitamin D do have some good effect in checking myopia, and I think it is a pity that a statement to the contrary should go unchallenged in the *Journal*.

Family Planning.—The General Secretary of the Family Planning Association writes: The quotations chosen by Dr. Clark (September 17, p. 656) from literature distributed by the Family Planning Association might lead readers to suppose that this association restricts its services to the classes of patients to whom he refers. I should like to point out that at all F.P.A. clinics (a list of which can be obtained from this office at 69, Eccleston Square, S.W.1, price 6d., post free) medical advice on contraception is available to all married women who attend. The F.P.A. would entirely agree with Dr. Clark's views that the size and spacing of the family is a matter to be decided by the parents who will have to take the responsibility of the welfare and upbringing of any children born to them.

SUPPLEMENT TO THE

BRITISH MEDICAL JOURNAL

LONDON SATURDAY OCTOBER 8 1949

THE SECRETARY REPORTS

HIGHER CIVIL SERVICE REMUNERATION

On February 26 this year attention was drawn in this column to the recommendations of Lord Chorley's Committee on the remuneration of higher Civil Servants. The following table summarizes some of the main recommendations of the committee, and compares them with the position at January 1, 1946, and with remuneration rates obtaining in 1939:

Administrative Class Salaries

Grade	1939	January 1, 1946	Chorley Committee Recommendation
Permanent Secretary to the Treasury ..	£ 3,500	£ 3,750	£ 5,000
Other permanent secretaries ..	3,000	3,500	4,500
Deputy secretary ..	2,200	2,500	3,250
Under secretary (a grade which existed in some departments only)	1,900	2,000	2,500
*Principal assistant secretary ..	1,700	—	—
Assistant secretary ..	1,150–1,500	1,320–1,700	2,000

* The grade of principal assistant secretary was abolished (although a few members of the obsolescent grade still remain) and the new grade of under secretary introduced into all departments.

The Chorley Committee made no recommendations for medical officers as such, but expressed the view that they should maintain their present relativities with the Administrative Class. The effect would be to bring the remuneration of the Chief Medical Officer of the Ministry to approximately £4,000 a year, as compared with £3,000 at present and £2,200 in 1939.

The Government accepted the recommendations made by Lord Chorley's Committee, but decided that they should be given effect by stages. The Chancellor of the Exchequer stated in the House of Commons in February this year that it was hoped to make a start in carrying out the recommendations before the end of the calendar year. Subsequently, it was stated that the commencing date for the first stage would be October 1, 1949. The second stage would have been given effect in October, 1950, and the third in 1951. The increases ranged from £300 to £1,250 a year for nearly 2,000 senior Civil Servants, and in the aggregate amounted to some £400,000 a year.

Last week the Government made the following announcement:

"On February 17 last the Chancellor of the Exchequer announced in the House of Commons the Government's acceptance of the recommendations made by the committee under the chairmanship of Lord Chorley for certain increases in the salaries of the higher grades of the Civil Service. He stated that the Government hoped to make a start in carrying out these recommendations before the end of the calendar year, and that they would be given effect by stages. It was subsequently decided that the commencing date for these changes was to be October 1 next, and the representatives of the grades concerned were so informed.

"The change in the exchange value of the pound and the consequent imperative need to avoid increases in personal incomes, if the country is not to lose the advantages which will otherwise accrue from that decision, have compelled his Majesty's Government to reconsider the position. They reaffirm their previous recognition that the increases of salary recommended are justified on their merits and that to give effect to them would not be in conflict with the policy of the White Paper on personal incomes.

"They also recognize that to postpone the beginning of the payment of these increases beyond the date which the staff concerned, with great public spirit, accepted will involve considerable sacrifice. None the less, his Majesty's Government feel that at this moment they could not reconcile the payment of these salary increases with the general policy of avoiding increases of remuneration which they are asking other sections of the community to accept.

"In these circumstances the Government have reluctantly decided that the introduction of the increases must be further deferred. It is hoped that the period involved will not be long. It is the Government's intention that, in any case, the arrangement made with the representative associations under which the full salaries recommended by the Chorley Committee are to become operative by October, 1951, will not be affected.

"Furthermore, the Government feel that this temporary further deferment of the increases already due should not be allowed to prejudice the pensions which will be payable to those officers who will retire during or soon after the period of this special abatement of salary. The Government are considering whether a direction which would achieve this object can be given under existing legislation, and if this is not possible they will introduce the necessary legislation"

Repercussions

In some minds the question may arise as to the repercussions of this decision. The discussions now proceeding with the Ministry on general practitioner remuneration are in effect based on the argument of the profession that the medical pool from which general practitioners are remunerated was only and could only be provisionally calculated before the Service came into operation, and should now be re-calculated in the light of certain known facts. For example, the pre-Act calculation of the central pool was based on the assumption that only 17,900 principals would share the pool. It is now known that the number of principals sharing the pool is substantially in excess of this number. Further, the so-called betterment factor of 20% was imposed by the Government, being mentioned as far back as 1946. To argue that this figure was set unduly low is perhaps an over-statement of the obvious.

On the other hand, in the case of the remuneration of higher Civil Servants the Government has agreed to certain increases. It commits itself to the policy of making those increases, agreeing what they should be. Where it has shifted its ground is the date on which a beginning should be made in effecting the increases. Further, it proposes to make some provision to secure that the delay in bringing the increases into operation should not affect adversely the pensions of those who would otherwise have benefited.

PURCHASE TAX ON CORSETS

EXEMPTION BY CERTIFICATES

In order that patients may be exempted from paying purchase tax on surgical corsets, medical practitioners give certificates describing the patient's infirmity and the type of corset required. The articles that may be obtained free of purchase tax are listed in Notice No. 78 (September, 1948) by the Commissioners of Customs and Excise. They are as follows:

Belts designed solely for use in cases of movable or floating kidney or colostomy.

Belts designed solely for use in cases of the following conditions:

Abdominal Diseases.—Severe enteroptosis, severe gastroptosis, severe visceroptosis, severe diverticulosis, hernia.

Diseases and Injuries of the Spine.—Actinomycosis, arthritis deformans, dislocation of the spine, carcinoma of the spine, fibrocystic disease of the spine, fracture of spine, fracture-dislocation of spine, osteochondritis juvenilis dorsi, osteomalacia, osteomyelitis of spine, sacro-iliac disease, spondylitis, tuberculosis of spine, poliomyelitis.

Deformities of the Spine.—Kyphosis, lordosis, scoliosis, spondylolisthesis.

Diseases of the Nervous System.—Cerebral diplegia, muscular atrophy, muscular dystrophy, paralysis of abdominal muscles, paralysis of spinal muscles, spinal neurosis.

Belts fitted with surgical pads or fitted with, or with provision for, surgical cups, chutes, disks or plates for post-operative wear, and belts (whether or not so fitted) specially designed to protect a recent abdominal incision.

ALLOWANCES TO PROFESSIONAL WITNESSES

A Home Office circular, dated September 8, 1949, states that the Minister of Health is now prepared to allow salaried hospital medical and dental staff in the National Health Service to retain fees paid to them for professional services not within the scope of the hospital and specialist services. Attendance at court as a medical witness, even though it does not involve loss of income, is regarded as being outside the scope of the Service.

The Home Secretary considers it reasonable that professional witness allowances should in future be payable to all salaried hospital doctors and dentists in the National Health Service, and Clerks of Courts have been instructed to amend, in this respect, the circular issued in August, 1948, which dealt with the payment of allowances to witnesses.

TEACHING HOSPITAL APPOINTMENTS

The Minister of Health, Mr. Aneurin Bevan, has made the following appointments to the boards of governors of teaching hospitals:

St. Thomas's Hospital.—Mr. C. R. N. Winn, in succession to Sir John Gilbert Laithwaite.

Hospital for Diseases of the Chest.—Lieut.-Com. H. Denton, R.N. (ret.), in succession to Sir Harold Scott.

Hammersmith, West London, and St. Mark's.—Professor Ian Aird, in succession to Professor J. H. Dible.

Royal National Orthopaedic Hospital.—Miss Grace Rattenburg, in succession to Mr. F. Bremner Coates.

St. Mary's Hospital.—Lady Plummer, in succession to Mrs. B. T. Compton.

United Oxford Hospitals.—Sir David Lindsay Keir, in succession to Sir Henry Clay.

United Manchester Hospitals.—Mr. A. Fielding, in succession to the Rev. G. H. Williams.

United Birmingham Hospitals.—Mr. C. A. F. Hastilow, in succession to Mr. E. W. Vincent.

Queen Charlotte's Hospital.—Mr. R. S. H. Thomas, to be secretary.

RETURNING MEDICINE BOTTLES

ALLOWANCE REDUCED IN SCOTLAND

The allowance which chemists receive for medicine bottles, boxes, etc., has been reduced in Scotland from 2½d. to 1½d. per prescription from October 1. Scotland now conforms in this matter with England and Wales, where the allowance was reduced on September 1 (*Supplement*, August 20, p. 94). It is estimated that this decision will save the taxpayer £70,000 a year.

Chemists will lose by it unless members of the public co-operate by returning empty medicine bottles. Labels will therefore be fixed to bottles asking patients to return them clean and promptly.

GENERAL PRACTICE IN LONDON

SHOULD BE OPEN AREA

The London Local Medical Committee met on September 27 and decided to inform the London Executive Council that in its opinion the whole of London should be regarded as an open area.

The Medical Practices Committee has classified (*Supplement*, August 6, p. 70) the following London boroughs in Schedule 3—i.e., "doubtful" places: Chelsea, Hampstead, Holborn, Kensington, Paddington, St. Marylebone, Wandsworth, and Westminster.

SICKNESS BENEFIT DRAFT REGULATIONS

The National Insurance Advisory Committee has been asked to consider and report upon preliminary draft regulations concerning sickness benefit. They enable claims for sickness benefit to be made in advance in long-term cases, and enable the Ministry of National Insurance to pay sickness benefit in appropriate cases before the formal award of the claim has been made by the independent statutory authority. The committee will consider written objections to them by or on behalf of persons affected if sent before October 28 to the secretary, National Insurance Advisory Committee, 6, Curzon Street, London, W.1.

Copies of the preliminary drafts of these regulations—the National Insurance (Claims and Payments) Amendment (No. 2) Regulations, 1949, and the National Insurance (General Benefit) Amendment (No. 2) Regulations, 1949—can be purchased price 1d. each from H.M. Stationery Office or any bookseller.

EMERGENCY BED SERVICE

NEW OFFICES OPENED

The Emergency Bed Service now has offices at the following addresses:

Central Office.—10, Old Jewry, London, E.C.2 (Monarch 3000). Area covered: By day, Central London only—i.e., the area not covered by the four branch offices. By night (9 p.m.–8.30 a.m.), the whole of Greater London.

Western Branch.—81, Mattock Lane, Ealing, W.13 (Ealing 6671). Area covered: Acton, Ealing, Hounslow, Staines, Uxbridge, Harefield, Northwood, Pinner, Harrow, Stanmore, Edgware, Mill Hill, Hendon, Willesden, Wembley, Brentford, and Twickenham.

Eastern Branch.—Langthorne Road, Leytonstone, E.11 (Leytonstone 6461). Area covered: Enfield, Edmonton, Chingford, Walthamstow, Leyton, Leytonstone, Stratford, Forest Gate, Plaistow, East and West Ham, Ilford, Barking, Romford, and Epping.

South-Eastern Branch.—Shooters Hill Road, S.E.18 (Woolwich 3471). Area covered: Woolwich, Greenwich, Blackheath, Lewisham, Catford, Eltham, Bexleyheath, Dartford, Sidcup, Orpington, and Sevenoaks. (Doctors wishing to place patients

in hospitals in the Bromley Group should normally ring the Bromley Group Admissions Office—Hurstway 2195.)

Another office will be opened at Wimbledon at the following address as soon as possible:

South-Western Branch.—Wimbledon I.D. Hospital, Gap Road, Wimbledon, S.W.19. Area covered: Wandsworth, Balham, Tooting, Streatham, Norwood, Croydon, Mitcham, Wimbledon, Richmond, Kingston, Surbiton, Epsom, Sutton, Morden, and Carshalton. (This area will be served by Monarch 3000 until the opening of the South-Western branch office, the date of which will be notified later.)

Last winter applications for the admission of patients were received at a greater rate than could be immediately dealt with, and it is hoped that these extended services will reduce delays to a minimum.

Questions Answered

R.A.F. Pay

Q.—*There appeared under "Questions Answered" (July 23, p. 57) a note about pay in the R.A.M.C. Arising from this I should be grateful if you would clarify the following points. You state that the pay of a captain after two years as such is £1 11s. per day. Does this apply equally to the R.A.F.? Also, and in reference to the R.A.F., does this rise to £1 11s. apply to the medical officers who were detained in the Service an extra three months owing to the emergency which was proclaimed last autumn? In other words, are such officers (flight-lieutenants) entitled to £1 11s. and not £1 8s. for that three-month period?*

A.—Yes, the pay of a flight-lieutenant in the medical branch of the R.A.F., after two years' service in the rank, is £1 11s. per day. The period of three months to which the questioner refers, and during which releases were suspended, counted for purposes of pay increments in the same way as other full-time paid service. Flight-lieutenants who had completed two years in the rank were therefore entitled to £1 11s. during that three-months period.

Payment for Dental Anaesthetics

Q.—*It has been my custom to administer a general anaesthetic for a dental colleague, usually for a complete clearance, and we have found it most convenient to use thiopentone soluble (pentothal). Since the introduction of the N.H.S. I have continued to supply the thiopentone soluble at my own expense. Is there any means of claiming for the cost of this anaesthetic agent? I asked the East Sussex Executive Council if I might prescribe it on Form E.C.10, but they replied that dental anaesthetics were not included in my terms of service, and that I could not do so. I would not raise the problem but for the fact that my colleagues inform me that it is their practice to so prescribe, and also where a single difficult extraction is involved my fee is 10s., of which 3s. is expended on the thiopentone.*

A.—The administration of a dental anaesthetic is not regarded as part of medical treatment and the regulations do not permit the re-stocking of materials used, whether it be nitrous oxide or thiopentone, on E.C.10. A dentist who calls in a doctor to give a general anaesthetic is paid a fee which is designed to cover the cost of both the anaesthetist's professional services and the materials which are supplied. The fee is actually paid to the dentist, who arranges for the appropriate payment to be passed over to the anaesthetist.

Locumtenency in a Partnership Practice

Q.—*(1) The locumtenent "holds the place of" the absent partner, and assumes the professional responsibilities of the absent partner in relationship to (a) the patients in the practice, (b) the remaining partner or partners, and (c) the law. Is the answer "Yes" or "No"?*

(2) The locumtenent, assuming the professional responsibilities of an absent partner, is therefore entitled to some of the privileges of partnership. "Yes" or "No"? For example, (a) an equitable distribution of work, both day and night, as between the locumtenent and the remaining partner or partners; (b) an equitable "off duty" rota as between the locumtenent and the remaining partner or partners.

A.—A locumtenent assumes the professional responsibilities of the absent partner in relationship to the patients and the remaining partner. As locumtenent he is responsible in law for his actions.

The question of whether the locumtenent is entitled to equitable distribution of work and off-duty time is entirely a matter for arrangement between the parties to any particular engagement. There are no general rules. The usual practice in this regard is for the locumtenent to undertake the work that would be done by the absent principal and, in reason, such duties as are allotted to him by the senior remaining partner. It is usual for a locumtenent to be allowed some off-duty time, depending to some extent on the type of engagement.

HEARD AT HEADQUARTERS

Anything Else, Madam?

The idea of the National Health Service as a big bowl into which anyone may dip and take what he wants spreads like ill news. One doctor has written to this office about a woman who, against the advice of the medical staff and of her own doctor, had her incontinent husband taken home from hospital. That may seem to tell the other way, but she has made matters even by, up to date, demanding from the Service an air-bed, a rubber bed-pan, a porcelain ditto, a urinal, cotton-wool, gauze, ready-made swabs, talcum powder, and surgical spirit, not to speak of supplies of medicines, tablets, and ointments. When it was pointed out to her that certain articles were not on the drug tariff, and that she would have to apply to the county council, her riposte was, "Well, could I have a tooth-brush for him?"

The Wrong Way to Look at it

As exasperating as the people who get more than their share out of the Service are the people who complain because they get nothing. The newspapers at the moment are full of them. One man writes that, although he has paid so much for the Service up to now—and it's fifteen months—all he has received in return is one free ride in an ambulance. He might have congratulated himself that he has had no occasion to want the Service. Such people ought to be told that they are getting a great deal out of it. Is it not worth while to pay something to have a healthier community at one's doors, just as it is worth while to pay an education rate to have a more literate one, even though one does not send one's children to a State school? To put it on the individual ground, is it not worth while for such correspondents to have their daily help absent less frequently with housemaid's knee, or their secretary with tennis elbow? Whether the Service is worth the cost is another matter, but to measure it by its personal return to oneself is the antithesis of good citizenship.

Believe It or Not

The Central Health Services Council has advised the Minister "that arrangements should be made to allow, under adequate safeguards, children in hospital to be visited by parents or guardians with reasonable frequency and, if necessary, by appointment." The Minister would be glad if hospital management committees and boards of governors would review the arrangements in force in their hospitals in the light of this advice.

Dangerous Drugs Act: Withdrawal of Authority

The Home Office announces that Dr. Geoffrey Roderick Richards (Port Talbot) is no longer authorized to be in possession of or to prescribe those drugs to which the Dangerous Drugs Regulations apply.

GENERAL MEDICAL SERVICES COMMITTEE

The following practitioners have been nominated by local medical committees, in the groups mentioned, for election as direct representatives on the General Medical Services Committee for the session 1949–50. The figures in parentheses indicate the number to be elected in each group.

GROUP "A" (4)	
GROUP "A1" S.E. Scotland	Dr. J. T. Baldwin, Penicuik, Midlothian Dr. N. B. Stewart, Edinburgh
GROUP "A2" N. of the Tay	Dr. J. R. Anderson, Fortrose Dr. A. C. Hendry, Bucksburn
GROUP "A3" City of Glasgow	Dr. J. T. McCutcheon, Glasgow
GROUP "A4" S.W. Scotland	Dr. R. C. Hamilton, Kilmarnock Dr. B. Hutchinson, Cambuslang
GROUP "B" (1)	
Northumberland, Durham, and County Boroughs therein	Dr. P. V. Anderson, Shildon, Co. Durham
GROUP "C" (2)	
Yorkshire (North, East, and West Ridings) and County Boroughs therein	Dr. H. F. Hollis, Leeds Dr. H. W. W. Price, Brighouse Dr. R. H. Sunderland, Bradford
GROUP "D" (3)	
Lancashire, Cumberland, Westmorland, and County Boroughs therein	Dr. C. Baxter, Liverpool Dr. P. S. Byrne, Westmorland Dr. A. Campbell, Accrington Dr. J. Stuart, Blackpool Dr. S. A. Winstanley, Manchester
GROUP "E" (2)	
Wales	Dr. D. B. Evans, Coedpoeth, Wrexham Dr. A. E. Jenkins, Pontypridd
GROUP "F" (1)	
Cheshire, Derbyshire, and County Boroughs therein	Dr J. B. Bennett, Hyde, Cheshire
GROUP "G" (1)	
Staffordshire, Shropshire, and County Boroughs therein	Dr. A. B. Davies, Walsall
GROUP "H" (1)	
Leicestershire, Lincolnshire (Holland, Kesteven, and Lindsey), Nottinghamshire, Rutland, and County Boroughs therein	Dr. G. Waring Taylor, Leicester
GROUP "I" (1)	
Herefordshire, Warwickshire, Worcestershire, and County Boroughs therein	Dr. W. D. Steel, Worcester
GROUP "J" (1)	
Berkshire, Buckinghamshire, Gloucestershire, Oxfordshire, and County Boroughs therein	Dr. H. G. Dowler, Gloucester Dr. W. Woolley, Bristol
GROUP "K" (1)	
Bedfordshire, Cambridgeshire, Huntingdonshire, Isle of Ely, Norfolk, Northamptonshire, Soke of Peterborough, Suffolk (East and West), and County Boroughs therein	Dr. A. Brown, Linton, Cambs Dr. J. C. Pearce, Diss, Norfolk
GROUP "L" (1)	
Cornwall, Devonshire, Isles of Scilly, Somerset, and County Boroughs therein	Dr. C. F. R. Killick, Williton, Somerset
GROUP "M" (1)	
Dorset, Hampshire, Isle of Wight, Wiltshire, and County Boroughs therein	Dr. H. S. Howie Wood, Shanklin, Isle of Wight
GROUP "N" (2)	
Kent, Surrey Sussex (East and West), and County Boroughs therein	Dr. A. W. Gardner, Lewes Dr. A. T. Rogers, Bromley Dr. D. F. Whitaker, Guildford
GROUP "O" (2)	
Essex, Hertfordshire, Middlesex, and County Boroughs therein	Dr. D. F. Hutchinson, Acton Dr. J. L. McKenzie Brown, Walthamstow
GROUP "P" (2)	
London	Dr. J. F. Murphy, London, S.W.8 Dr. H. H. D. Sutherland, London, W.10
GROUP "Q" (1)	
Northern Ireland	*No nomination*

The voting papers in those areas in which there is a contest (i.e., groups A1, A2, A4, C, D, J, K, and N) were posted on October 3.

WORLD MEDICAL ASSOCIATION

The General Assembly of the World Medical Association is meeting at B.M.A. House between October 10 and 16. During that week there will be some dislocation of the ordinary routine at B.M.A. House, particularly in the service of lunch in the Members' Common Room. Members wishing to take lunch during the W.M.A. Meeting are asked to do so as early as possible—i.e., between 12 and 1.

Correspondence

Fees for Professional Witnesses

SIR,—For some years past the Medical Defence Union has been actively engaged in seeking to secure adequate payment for practitioners appearing as medical witnesses to fact, or as expert witnesses in civil and criminal cases.

In September of last year the Witnesses Allowances Regulations, 1948, were published. These defined the fees payable to professional and other witnesses attending to give evidence in criminal courts. After all the work put into this matter it had been hoped that the new regulations would show a marked improvement in the payment of professional witnesses and an honest recognition of the value of the service involved. The allowances specified, it should be noted, are maximal allowances, higher it is true than those payable under the previous regulations, but lower than those considered by the profession to be equitable.

Correspondence reaching the offices of the Medical Defence Union shows that many practitioners are regarded as ordinary witnesses. They frequently receive not more than 5s. per day for attending at court to give professional evidence on matters of supreme importance. One member attended three full days and received 15s. in all. On investigation it was ascertained that this state of affairs derived from a directive from the Home Office instructing Clerks of the Assize, of the Peace, and to the Justices that allowances were not to be paid to salaried officers who did not lose remuneration by their attendance at court. Protests were lodged with the Home Office that all medical witnesses were entitled to proper fees for the time and trouble involved in the preparation and in the giving of their evidence, irrespective of any overriding requirement that might be included in the terms of the officers' employment to refund such fees to the employing authority, or any immunity from a proportionate loss of salary for absence from duty to attend a court.

After several exchanges on this matter, the Home Office in a letter issued in July of this year indicated that the Secretary of State understood that the Ministry of Health had communicated proposals to the medical profession whereby attendance at court hearings as medical witnesses would be regarded as work falling outside the scope of hospital and specialists services, and that the fees for such work could be retained by the practitioners concerned.

Waiting for a decision on this matter did not meet with acceptance by the council of the Medical Defence Union. It consequently instructed its solicitors to take action in certain specially selected cases in order to test the situation exhaustively. In one letter just received by our solicitors the matter appears to have resolved itself satisfactorily. This letter emanates from a Clerk of Assize and the material sentence is as follows: "I beg to inform you that an order has been given by the Secretary of State requesting that professional witness allowances should in future be paid to all salaried hospital doctors and dentists." The writer concluded his communication by intimating that the doctor would receive payment of his fees in due course.

This cancellation of the offending directive marks the successful conclusion of an offensive which should never have been necessary. It is not admitted, of course, that the fees payable now are anything like adequate or that they should be of a maximal character, leaving a discretion to clerks to determine within the range specified the actual sum to be paid for any professional service. That aspect of the struggle must be continued with the assistance of all who are interested in this matter.—I am, etc.,

London, W.C.1. ROBERT FORBES,
Secretary, Medical Defence Union.

*** A note on fees for professional witnesses appears at page 160.—ED., *B.M.J.*

Doctors and Dentists

SIR,—The correspondence in the *Supplement* on the subject of the N.H.S. and airing the unhappy lot of medical practitioners in contrast with that of dental surgeons and dentists, who might be thought to be in clover, has not so far acknowledged the fact that studentship towards registration bears more heavily on the dental student. Costs, in time and money, are subjoined herewith. These are official figures, which may be an eye-opener to some who are in ignorance.

UNIVERSITY OF GLASGOW

Medical fees for 6-year course	£300
Dental fees for 5-year course	
Fees	£280
Equipment	£75
Total	£355
Duration of Medical course in months	
Four years of 7½ months	30 months
Two years of 10 to 11 months	22 months
Total	52 months
Duration of Dental course in months	
One year of 8 months	8 months
Four years of 11 months	44 months
Total	52 months

Speaking as one who has a foot in both fields, it has appeared to me that there is an unnecessary tendency to disparage the dental surgeon. His training is that of a specialist, and that fraction of the dental profession which was registered in 1901 without having the qualification L.D.S. may be fairly stated to be trying quite seriously in most cases to raise their professional standards. It is to be noted also that the dental profession did make a more earnest fight against the iniquities and degradation of the N.H.S. than the medicals appear to have done.—I am, etc.,

Glasgow. W. FERGUSON MACKENZIE.

Principals and Assistants

SIR,—I have read the correspondence in the *Supplement* about assistants with a considerable amount of partisan feeling—being myself yet "another assistant." "P.Q.R." (*Supplement*, August 27, p. 118) asks, "How much better off is the principal?" My reply is this. First, that he has got a permanent position and his own future to make or mar, depending solely on his ability and willingness to succeed. Secondly, though he was probably not thinking of this when he wrote, he will be well off insomuch as he continues to attract patients and work for them after he has taken in an assistant. If he cannot do this he is manifestly unfit to employ an assistant.

No assistant can feel *en rapport* with a principal who buys his ease by taking an assistant to whom he will give no definite assurances of partnership; and worse still is the principal who endeavours to keep his practice going with an assistant to whom he makes promises of partnership in the ever-receding future, or, worse again, attempts to further his own interests by employing a succession of assistants who serve under what is virtually a protracted locum's agreement, "on probation," until in the natural course of events they cannot stick the uncertainty any longer and resign, leaving the way open for another young hopeful. Or of course they may get the sack for demanding that their labours be rewarded. All such employers I have known in my four-years career of general practice since being released from the Forces; and like "X.Y.Z." (*Supplement*, September 17, p. 140) I have lasted from between six months to one year in each job.

I will not speak of my finances, because I do not suppose they are much worse than those of any other young married man (I have two children) of my age, war service, and class (I mean the so-called professional class). Also, anyone can live through lean years, carefully watching an overdraft, if he has some assurance of a future. It is the lack of assured prospects for the assistant in general practice that appals me. All my engagements were concluded with the strict understanding that I was an "assistant with a view": all I had to do was to work, and after a trial period (generally short) I would be a junior partner; with certainly no princely salary at first, but, and this is the important point, I would be settled, with no fear of the sack, and a chance to build up a future.

Young married assistants want too much in the eyes of the principals. They not only want to gain experience from their work, they want definite assurances and the means to educate a family. And this is where we go begging from job to job. We cannot tolerate permanent, or view-in-the-remote-future, assistantships while our families are growing up round us. Nor are we rolling stones who can roam from job to job seeking experience of medical life. In point of fact I could not afford time from my present job to go and seek a new Mecca: every week without work is a week without pay, to say nothing of the overburdening cost of a fourth move of house and home.

I say, then, that it is time that the position of experienced married assistants was urgently reviewed in all responsible quarters; and, furthermore, if nothing is done to right this unjust anomaly of an employer–employee relationship, *within the structure of State contract service*, more and more young men will be disheartened and driven out of general practice and even out of the country.

The only solution is for the Ministry to consider supporting experienced assistants, in their own right, as men entitled by the nature of their work (and common need) to run or share in the running of a practice, particularly when the Government is subsidizing the salaries of trainee-assistants so that principals can easily afford to pay them—and do pay them—more than the salaries of many already engaged senior assistants. The only other solution is for a change of heart among principals, who should set a lower target for their personal incomes, both for the good of general practice in England and for the good of the patient, who gets disheartened by being visited by a succession of young men sent by Dr. So-and-So. I fear that such a change of heart, though desirable, is psychologically unlikely.—I am, etc.,

ASSISTANT-WITH-VIEW.

Payment of Locums

SIR,—"An Occasional Locum" (*Supplement*, September 17, p. 140) might be interested in my recent experience. I paid a locum £3 3s. a day and £2 2s. a week car allowance. The week before I went away I did 46 visits; the week after I returned I did 64 visits. In the whole 15 days I was away he did 31 visits. My locum during the same period last year did 87 visits.

For days after I returned I had numerous complaints from patients who had not been visited, from others of visits sent in

before 10 a.m. which were not done until late evening, and from my colleagues who had had to do day and night visits for me because my locum could not be found. There were no maternity cases at all during this period. He seemed to be rarely available day or night. To crown it all my garage account shows that for the 31 visits in the 15 days he had apparently used, at my expense, as much petrol as I use in two months. Which of us was exploited?

Of course there are good and bad principals. There are also good and bad locums and assistants. As for "X.Y.Z." in the same issue, if he is getting a salary of £200 a year less than that advertised for trainee assistants, he is either a fool and deserves to be exploited, or perhaps that is all his services are worth. I would not employ my recent locum if he offered to pay me a salary for doing so.

As for all this talk of exploitation, now that partnerships have to be given away assistants consider themselves badly treated if they are not given a substantial partnership after a few months. Let "X.Y.Z." and others remember that nowadays the one giving away the partnership takes all the risks. When they had to be bought the buyer usually took the main risk. Just as the buyer was very particular in those days, so are those who have to give them away nowadays.

Assistants' salaries are, on the whole, at least twice what they were pre-war. This compares most favourably with salary increases in other professions. To talk about slave labour and exploitation is sheer nonsense. The principals of to-day were the assistants of yesterday. If "X.Y.Z." gets rid of his persecution complex he will find his Shangri-La. When he does I have no doubt he will pay his assistant a truly princely salary, do all the night-work himself, and give away a substantial partnership just as soon as he is asked for it.—I am, etc.,

PRINCIPAL.

Association Notices

OPHTHALMIC GROUP COMMITTEE

The following were the successful candidates in the election held recently to fill vacancies in the Ophthalmic Group Committee caused by retirement of members at the end of the 1948–9 session:

H. R. Bickerton (representing Region 1).
Nigel Cridland (representing Region 3).
P. Jameson Evans (representing Region 2).
C. M. Stevenson (representing non-members of the Group on the Central Ophthalmic List).
F. Oliver Walker (representing Region 5).

DISSOLUTION OF LANCASHIRE AND CHESHIRE BRANCH, AND FORMATION IN PLACE THEREOF OF MANCHESTER AND EAST CHESHIRE, MERSEYSIDE, AND NORTH LANCASHIRE BRANCHES

Notice is hereby given by the Council that the Lancashire and Cheshire Branch has been dissolved, and that the following Branches have been formed in place thereof:

(1) A Manchester and East Cheshire Branch, coterminous with the areas of the following Divisions of the Lancashire and Cheshire Branch: Ashton-under-Lyne, Bolton, Bury, Crewe, Hyde, Leigh, Macclesfield and East Cheshire, Manchester, Mid-Cheshire, Oldham, Rochdale, Salford, Stockport, Wigan;

(2) A North Lancashire Branch, coterminous with the areas of the following Divisions of the Lancashire and Cheshire Branch: Blackburn, Blackpool and Fylde, Burnley, Furness, Lancaster, Preston;

(3) A Merseyside Branch (*Supplement*, July 16, 1949).

The Manchester and East Cheshire and North Lancashire Branches come into existence as from the date of publication of this notice.

CHARLES HILL,
Secretary.

ADJUSTMENT OF AREAS OF CORNWALL AND PLYMOUTH DIVISIONS

With reference to the notice published in the *Supplement* of September 3, 1949 (p. 126), the area of the Municipal Borough of Launceston has also been transferred from the Cornwall Division to the Plymouth Division.

CHARLES HILL,
Secretary.

NOTICE TO SHIP SURGEONS

BRITISH MEDICAL ASSOCIATION—MARITIME SUBCOMMITTEE

The Private Practice Committee of the British Medical Association has reappointed for the current session a subcommittee to consider all questions affecting medical practitioners concerned with merchant shipping.

The subcommittee will hold its first meeting of the session at B.M.A. House, Tavistock Square, W.C.1, on Thursday, October 20, at 11 a.m., and any doctors in active practice as ship surgeons who find it convenient to attend are invited to do so, if possible giving notice by letter or telephone of their intention to come.

CHARLES HILL,
Secretary.

Diary of Central Meetings

OCTOBER

14	Fri.	Committee on Industrial Health Services in relation to the National Health Service, 2 p.m.
17	Mon.	Psychological Medicine Group Committee, 2 p.m.
18	Tues.	Proprietary Medicines Committee, 11 a.m.
18	Tues.	Committee on the Association of the General Practitioner with Hospitals, 2 p.m.
18	Tues.	Building Committee, 2 p.m.
19	Wed.	Film Committee, 2.30 p.m.
20	Thurs.	Committee *re* Salaries of Medically Qualified Teachers, etc., 2 p.m.
20	Thurs.	Occupational Health Committee, 2 p.m.
21	Fri.	Public Health Committee, 1.30 p.m.
21	Fri.	Venereologists Group Committee, 2.30 p.m.
28	Fri.	Science Committee, 2 p.m.

2	Wed.	(At Lion Hotel, Shrewsbury) Welsh Committee, 2.15 p.m.
3	Thurs.	Committee on Industrial Health Services in relation to the National Health Service, 2 p.m.
9	Wed.	Committee on the Postgraduate Education of General Practitioners, 11 a.m.

Branch and Division Meetings to be Held

CITY DIVISION.—At St. Leonard's Hospital, Nuttall Street, Kingsland Road, London, N., Tuesday, October 11, 8.30 p.m., Dr. E. W. Taylor: "London's Water Supply."

CLEVELAND DIVISION.—At Sparks Café Royal, Middlesbrough, Thursday, October 13, 7 for 7.15 p.m., Supper, followed by address by Dr. I. G. W. Hill: "Treatment of Hypertension."

HALIFAX DIVISION.—At Royal Halifax Infirmary, Wednesday, October 12, 8.30 p.m. Annual general meeting. Election of officers, etc.

HENDON DIVISION.—At Hendon Hall Hotel, Tuesday, October 11, 8.15 p.m., Dr. Paul Pincus: "New Research on Dental Caries." Film and slides.

SOUTH ESSEX DIVISION.—At Oldchurch Hospital, Romford, Friday, October 14, 9 p.m., Dr. H. K. Cowan: "The Domiciliary Maternity Service, Health Centres, and other County Medical Services."

SOUTH-WEST ESSEX DIVISION.—At Thorpe Coombe Maternity Hospital, Forest Road, Walthamstow, E., Wednesday, October 12, 8.30 p.m., clinical meeting. Two lectures on the Rhesus Factor. (1) Dr. Gertrude Plaut: "Some Recent Advances in Rhesus Factor Work"; (2) Dr. E. Hinden: "Erythroblastosis of the Infant."

SOUTH-WEST WALES DIVISION.—At St. David's Hospital, Carmarthen, Sunday, October 9, 2.30 p.m., lecture by Dr David G. Morgan (Cardiff): "The Hospital Service under the N.H.S. Act and in the Future."

MALARIA

WITH SPECIAL REFERENCE TO CERTAIN EXPERIMENTAL, CLINICAL, AND CHEMOTHERAPEUTIC INVESTIGATIONS*

BY

N. HAMILTON FAIRLEY, C.B.E., M.D., D.Sc., F.R.C.P., F.R.S.

Wellcome Professor of Tropical Medicine, London School of Hygiene and Tropical Medicine; Physician, Hospital for Tropical Diseases, University College Hospital, London

LECTURE I: THE LIFE CYCLE

Under the stimulus of war in the Tropics, more scientific effort and medical man-power were directed to intensive study and research on malaria than to any other disease in history. In such circumstances it is hardly surprising that great advances in our knowledge of this disease and of its control have resulted during the past decade.

The discovery of insecticides like D.D.T. and "gammexane" is now leading to the control of mosquito-breeding and the destruction of adult mosquitoes on a scale which is revolutionary. Similarly, the synthesis of new antimalarial drugs in the U.K. and the U.S.A. proceeded on a scale that far surpassed all previous achievements and brought the control of malaria by chemotherapeutic means within the range of practical possibility. In connexion with the discovery of proguanil (paludrine) by Curd, Davey, and Rose (1945) over 1,000 new compounds were produced and tested against bird malaria. In the United States over 14,000 new compounds were screened for their therapeutic action in bird malaria, and over 100 of these were subsequently tested on man. The most promising of the antimalarial drugs synthesized in U.S.A. and U.K., such as certain sulphonamides, mepacrine, "sontochin," "chloroquine," and proguanil, were tested for suppressive and prophylactic action on experimentally infected volunteers living under tropical conditions by Australian medical research units established near Cairns, in Northern Queensland.

The discovery made by Shortt and his colleagues last year of the pre-erythrocytic and exo-erythrocytic cycle in monkey malaria (*Plasmodium cynomolgi*) and of pre-erythrocytic schizonts in benign tertian malaria in man was long overdue, establishing as it did the tissue phase in mammalian malaria some fifteen years after its demonstration in avian malaria. It was a discovery of outstanding importance not only from the parasitological point of view but also because of its clinical and chemotherapeutic implications. This first lecture will be devoted to this subject.

*First of the Croonian Lectures delivered at the Royal College of Physicians of London on May 3 and 5, 1949.

Erythrocytic and Sporogonous Cycle

At the beginning of the present century the life cycle of the malaria parasite appeared to be completely known. A schizogonous cycle in the red cells which accounted for clinical attacks and a sporogonous cycle in the mosquito had been firmly established. It is true Grassi (1900) had considered there might be another developmental cycle in man during the incubation period, but after Schaudinn (1902) vividly described just how the sporozoites actively penetrated the red cells the chain of events in the life cycle appeared complete. The whole question was reopened some thirty years later mainly because it was not possible to explain the behaviour of antimalarial drugs like quinine and "plasmoquine" (pamaquin) on this basis.

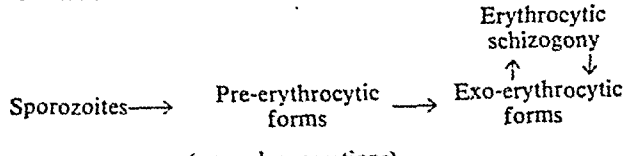
Sergent and Sergent (1922) had noted that though quinine destroyed malaria parasites once they appeared in the blood it exerted no therapeutic action when given during the incubation period. Yorke and Macfie (1924) next reported that quinine given during the incubation period resulted in radical cure of benign tertian malaria which had been transmitted by blood inoculation (trophozoite-transmission), whereas it merely prolonged the incubation period slightly when the disease was transmitted by infective mosquitoes (sporozoite-transmission).

In a paper read before the Royal Society of Tropical Medicine and Hygiene in January, 1931, James (1931a) confirmed these observations and discussed several views which had been put forward to explain the different therapeutic response induced by quinine in patients infected by blood inoculation and those infected by mosquitoes. One theory was that some of the sporozoites, instead of entering the red blood corpuscles, entered connective-tissue cells or the cells lining the capillary blood vessels; another theory was that the sporozoites actually penetrated into the interior of the red cell, whereas merozoites merely attached themselves to the outside of the corpuscle. James favoured the latter view and considered that Schaudinn's account of the penetration of the corpuscle by the sporozoite was "so clear-cut and detailed as to admit

of no question." In the discussion which followed, Warrington Yorke (1931) was frankly sceptical, stating that he had spent some weeks trying to repeat Schaudinn's observations without success.

In August of the same year, James, Nicol, and Shute (1931) reported the prevention of mosquito-transmitted benign tertian malaria in volunteers by the use of pamaquin: 20 mg. was given on the day before infection, and 60 mg. for the next six days. James (1931b) considered that these findings regarding pamaquin favoured the conception that the malaria parasites passed through a tissue stage and, in a communication read by Schüffner at Amsterdam in December, suggested that the time had come "to consider whether knowledge concerning the life cycle of the malaria parasite was complete or not." He pointed out that Schaudinn's observations had never been confirmed, that sporozoites were essentially parasites of tissue cells, and suggested that possibly, on entering the blood, they were carried to reticulo-endothelial cells of the lungs and other organs, where they underwent "a cycle of growth or sporulation similar to the cycle of the allied bird parasite, *Halteridium*."

Tissue-phase Parasites in Avian Malaria



The hypothesis that there was a tissue phase of the parasite soon received support from the discoveries made in bird malaria, but it took another ten years' intensive experimental work to complete the story.

Garnham (1948), in his excellent review on this subject, regards Raffaele (1934, 1936) as probably being the first investigator to recognize the significance of exo-erythrocytic parasites in bird malaria, though undoubtedly many observers had seen them much earlier. The important publications of Huff and Bloom (1935), Brumpt (1937), and James and Tate (1937, 1938) followed shortly after those of Raffaele.

Two distinct schizogonous cycles have been recognized in the tissues: (1) the pre-erythrocytic, which occurs during the incubation period before asexual parasites appear in red blood corpuscles; and (2) the exo-erythrocytic schizogony, which is found after parasites have gained access to the corpuscles and persists in the late stages of the infection.

In seven species of plasmodia producing malaria in birds, Porter (1942) differentiated between two types of exo-erythrocytic schizogony—one occurring in *P. gallinaceum* and the other in *P. elongatum* infections. Schizogony of gallinaceum type occurred mainly in the reticulo-endothelial system, that of elongatum type was confined to the wandering cells of the blood and haemopoietic organs.

The salient features in the tissue cycle in avian malaria, modified from Davey (1944), are diagrammatically represented thus:

1. *Pre-erythrocytic Schizogony.*—The pre-erythrocytic forms in *P. gallinaceum* were first discovered by Mudrow (1940) and Shortt, Menyon, and Iyer (1940). A few years later Huff and Coulston (1944) injected enormous numbers of sporozoites into localized skin areas in chicks, demonstrating that sporozoites penetrated the reticulo-endothelial cells of the skin in from half an hour to six hours and underwent a schizogonous cycle lasting 42 hours. Primary forms also developed in the spleen and other organs intercurrently. When the schizont ruptured, the first-generation merozoites (cryptozoites) penetrated adjacent reticulo-endothelial cells, where they underwent one or more schizogonous cycles before liberating second- or third-generation merozoites (metacryptozoites) into the blood. By the fifth day Reichenow and Mudrow (1943) distinguished two types of schizonts—the macroschizonts containing 100–200 macromerozoites which are destined to invade fresh reticulo-endothelial cells, and the microschizonts containing up to 1,000 micromerozoites which invade the red blood corpuscles. Sub-inoculations with saline suspension of organs containing pre-erythrocytic parasites consistently yield positive results in avian malaria.

2. *Exo-erythrocytic Schizogony.*—Little difference has been observed between the pre-erythrocytic and the later exo-erythrocytic schizonts; pigment is absent from both, since they develop in cells containing no haemoglobin. The distribution of exo-erythrocytic schizonts in the organs has been described by several different workers. James and Tate (1937, 1938), who independently described the schizogonous cycle in the reticulo-endothelial cells and monocytes of fowls infected with *P. gallinaceum*, first suggested that the non-committal title "exo-erythrocytic" be used to differentiate it from erythrocytic schizogony. They found that the brain, liver, lungs, and spleen were important sites for the tissue stages, and that, even after the erythrocytic parasites had disappeared from the blood with quinine treatment, birds died from blockage of the vessels of the brain resulting from schizonts developing in the reticulo-endothelial lining.

Coulston and Manwell (1941) actually produced experimental infections with *P. circumflexum* by the injection of a single parasitized corpuscle, and after several passages exo-erythrocytic forms appeared. After intravenous inoculation of blood containing *P. gallinaceum*, Tullis (1947) found that small numbers of exo-erythrocytic schizonts appeared on the fourth day in reticulo-endothelial cells of the spleen and on the sixth day in the liver, heart, lungs, and intestine. Thus in bird malaria tissue schizonts may originate directly from pre-erythrocytic parasites or indirectly from the blood parasites.

Tissue-phase Parasites in Monkey Malaria

In monkeys, malaria which is caused by *P. cynomolgi* is readily transmitted experimentally by *Anopheles maculipennis atroparvus*. Other well-known simian parasites, like *P. knowlesi* and *P. brazilianum*, are unfortunately unsuitable for studying tissue forms, since the mosquito vector is unknown.

In *P. cynomolgi* infections the erythrocytic parasites closely resemble vivax parasites morphologically and appear in the blood about the ninth day. Relapses are common up to six to eight months, when spontaneous cure generally occurs. Coatney and Cooper (1948) report that pentaquine and pamaquin with or without quinine bring about radical cure. The disease closely resembles benign tertian malaria in man, especially the New Guinea and Chisson strains characterized by short-term relapses. Much intensive research work has been undertaken in America, India, England, and other parts of the world during the past decade in an effort to demonstrate tissue forms in monkeys infected with this species of plasmodium. It was not until last year, however, that Shortt, Garnham, and Malamos (1948), at the London School of Hygiene and Tropical Medicine, discovered pre-erythrocytic forms in the liver of a monkey (*Macaca mulatta*) intensely infected with sporozoites seven days previously.

1. *Pre-erythrocytic Parasites.*—In this experiment over 500 hyperinfected mosquitoes (*A. maculipennis atroparvus*) were

first fed on this monkey; then the entire batch was ground up with heparinized plasma and injected parenterally. The pre-erythrocytic forms were confined to the parenchyma cells of the liver, sections of which showed ovoid blue areas, averaging about 26 μ in diameter, composed of plasmodial masses containing chromatin particles. Later work showed that mature schizonts on the eighth or ninth day contained nearly 1,000 merozoites; each merozoite measured a little over 1 μ in diameter and was composed of a mass of cytoplasm with a small fragment of chromatin on one side. When the schizont ruptured, the merozoites escaped into the circulation via the hepatic sinusoids, and invasion of the residual mass by lympho-macrophage cells, plasma cells, and polymorphonuclear cells occurred. Pre-erythrocytic schizogony in *P. cynomolgi* was later confirmed by Hawking, Perry, and Thurston (1948).

2. *Exo-erythrocytic Forms.*—Some months later Shortt and Garnham (1948) demonstrated the late tissue stages (exo-erythrocytic schizonts) in the parenchyma cells of the liver of a monkey which had been hyperinfected 103 days previously; by this time the disease was latent and parasites had temporarily disappeared from the peripheral blood. The late exo-erythrocytic forms resembled the pre-erythrocytic forms in most respects, a possible difference being the presence of a limiting membrane surrounding the younger schizonts. These exo-erythrocytic forms undoubtedly represent the relapse forms. Shortt and Garnham (1948) consider that exo-erythrocytic schizogony is maintained throughout the whole course of the disease, and that the cellulo-humoral antiparasitic defence mechanism of the host is operative only against the erythrocytic parasites, resulting in the destruction of merozoites entering the circulating blood. This immunity mechanism, which comes into play exclusively against the erythrocytic parasite, is not active against the exo-erythrocytic forms themselves, possibly because of their intracellular habitat. Those merozoites destined to invade other liver cells are similarly protected, so that the exo-erythrocytic cycle can go on indefinitely quite independently of blood infection.

Comment.—The success attained by Shortt and his colleagues, where so many others had failed, was no doubt due to the intense hyperinfection adopted and the improved technique devised for staining tissue parasites. In the monkey it involved the introduction of hundreds of thousands of sporozoites by mosquito-bite and by inoculation either of a whole mosquito intraperitoneally or of the salivary glands intravenously (Garnham, 1948). Investigators had also been misled to some extent because the tissue phase in mammalian malaria differed in certain unexpected ways from avian malaria. Thus in monkey malaria schizogonous development takes place in the parenchymatous cells of the liver, not in reticulo-endothelium, while subinoculation with saline suspensions of the liver into clean monkeys invariably yields negative results, probably because there is only one generation of pre-erythrocytic schizonts whereas in avian malaria there are several.

TISSUE-PHASE PARASITES IN HUMAN MALARIA

A. Benign Tertian Malaria

Pre-erythrocytic Phase.—Shortt, Garnham, Covell, and Shute (1948) also reported the pre-erythrocytic stage of *P. vivax* in a volunteer patient who had been exposed to heavy biting by infected mosquitoes (*A. maculipennis atroparvus*) and had in addition received an intravenous injection of sporozoites derived from their salivary glands. Laparatomy and liver biopsy were performed seven days later under local analgesia. Sections revealed plasmodial masses in the parenchyma cells, measuring up to 42 μ in diameter, which were studded with chromatin particles and some of which contained vacuoles. In appearance they closely resembled the pre-erythrocytic schizonts found in *P. cynomolgi* in monkeys.

From subinoculation experiments undertaken by Fairley (1945) and Fairley *et al.* (1947) it is evident that vivax sporozoites after being inoculated by mosquitoes rapidly gain access to the blood but soon again leave the circulation, invading the parenchyma cells of the liver, as shown by Shortt and his colleagues. Here they pass through a prolonged developmental cycle lasting at least eight days. The mature schizonts rupture and merozoites enter the circulation with great regularity on the ninth day of infection, producing a subpatent parasitaemia which may last another one to seven days. In thick films scanty parasites—i.e., to the order of 1 per c.mm.—appear on an average 12 days after exposure (range 10–15 days). This at least is the chain of events so far as the New Guinea strain of *P. vivax* is concerned.

Exo-erythrocytic Forms.—There is so much indirect clinical evidence supporting the presence of persistent exo-erythrocytic forms in benign tertian malaria, and vivax infection with short-term relapses is so similar to cynomolgi malaria, that for all practical purposes their existence can be accepted. Latency and the tendency to multiple relapses can best be explained on the basis of persisting exo-erythrocytic forms, while the different therapeutic response to various schizonticidal drugs like mepacrine, chloroquine, and quinine observed in blood-inoculated and mosquito-transmitted malaria is otherwise inexplicable. The schizonticidal drugs rapidly produce radical cure in trophozoite-transmitted vivax malaria. In sporozoite-transmitted malaria, though they rapidly produce clinical cure and clear the blood completely of parasites as revealed by negative subinoculations and negative blood smears, parasites later reappear and overt relapses follow. To establish radical cure during the overt attack one of the 8-amino-quinoline compounds like pamaquin or pentaquine is given in full dosage in combination with quinine. During the long latency characteristic of the St. Elizabeth strain of *P. vivax* radical cure has been reported by White *et al.* (1948) at a time when erythrocytic parasites are entirely absent from the blood: such a result can be due only to exclusive action on exo-erythrocytic forms.

Exo-erythrocytic Forms and Immunity Response.—According to Shortt and Garnham (1948) exo-erythrocytic schizogony is maintained throughout the whole course of the disease, and the antiparasitic defence mechanism of the host is directed essentially against the erythrocytic parasites, not against pre-erythrocytic or exo-erythrocytic forms. They suggest that latency and relapse in vivax malaria are governed by this immunity defence mechanism. Acquired antiparasitic immunity and tolerance result from a specific cellulo-humoral response to the invasion of the blood by erythrocytic parasites—provided that the parasitaemia is of sufficient duration and intensity to elicit an adequate response. The experimental studies of Taliaferro and Mulligan (1937) indicate that the spleen, liver, and bone marrow undergo considerable lymphoid hyperplasia with cytogenesis of macrophages, parasites being mainly destroyed locally in these organs. Immunity is paid for in terms of blood destruction, overworked sweat glands, and fever, but it is more easily acquired with some vivax strains than with others. Whether it is complete or partial will be determined by the trophozoite experience of the individual (total antigenic stimulus) and the strain of *P. vivax* implicated. With New Guinea strains solid immunity results in untreated patients only after prolonged primary fever, or if this be cut short by antimalarial

therapy it may arise later during febrile relapses in which treatment is withheld or markedly delayed.

Latency and Relapse

1. *Latency with Immunity.*—Blackburn (1948) was able to show that volunteers infected with the New Guinea strain of *P. vivax* who developed solid tolerance and antiparasitic immunity to their infections constantly had vivax trophozoites in the peripheral circulation, though their density rarely exceeded 1 per c.mm. over several months of observation. Gametocytes were never seen during the period of immunity, and mosquitoes fed on these subjects failed to become infected. The low densities of trophozoites caused no constitutional disturbances whatsoever. These volunteers had normal haemoglobin concentrations and red blood cell counts, their spleens were not palpable, and they were perfectly fit. Attempts to induce relapses by reinfection with the same strain of *P. vivax* (superinfection) were unsuccessful.

2. *Latency and Suppression with Mepacrine.*—In experimentally infected volunteers taking 0.1 g. of mepacrine daily for many months, Fairley and his colleagues (1945, 1947) found that vivax parasites were not demonstrable in thick smears, that subinoculations invariably became positive on the 9th day and were generally negative after the 14th day of infection. In one patient receiving 50 infective vivax bites on zero day, subinoculations with 20 ml. of blood were made at four-day intervals between the 9th and 142nd days while receiving suppressive mepacrine. Positive results were recorded on the 9th, 13th, and 42nd days after infection; the remaining 32 subinoculations were negative. Parasites were absent in blood films on the 42nd day, when the positive subinoculation occurred. Overt vivax malaria occurred on the 177th day, 35 days after mepacrine ceased. It is noteworthy that in heavy experimental infections the 42nd day is about the time the first relapse appears in patients whose primary fever has been treated with schizonticidal drugs. After stopping suppressive mepacrine overt vivax malaria occurred within three to ten weeks in 97% of cases. No evidence of immunity was observed in these patients: this is hardly surprising, as merozoites are destroyed shortly after reaching the blood with the New Guinea strain of *P. vivax*, provided the plasma mepacrine concentration is satisfactory.

When suppressive drug medication is stopped overt attacks occur in a few weeks with the ordinary New Guinea and the Chisson strain of *P. vivax*, which have a close relapse pattern, but with the St. Elizabeth, Madagascar, and local Dutch strains, which have had suppressive treatment during the first four weeks after infection, overt malaria does not appear until approximately nine months after the original infection.

3. *Latency and Long-term Relapse without Immunity.*—True latency with long-term relapse is encountered with certain strains of *P. vivax* both in natural infections and where the primary fever has been suppressed by antimalarial drugs or treated early in the febrile attack.

(*a*) *Latency Following Suppression of Primary Fever.*—Important experimental investigations in volunteer prisoners in the U.S.A. have recently been carried out with the St. Elizabeth strain of *P. vivax*. This strain produces an infection with a long latent period of eight to nine months between the early treated primary attack and the first relapse; thereafter a series of short-term attacks begin. White *et al.* (1948) report the complete absence of circulating parasites during this long latent phase; thick blood smears were always negative, and massive subinoculations with 250–300 ml. of blood to non-immune recipients failed to produce malaria. In addition Cooper *et al.* (1947) report that during this period the individual harbouring a latent infection is susceptible to superinfection with parasites of the same strain, indicating that no immunity has developed. Coatney and Cooper (1948) conclude that it is impossible to account for this long latent interval on the basis of immunity to erythrocytic parasites, and suggest that it may represent a period when the fixed-tissue reservoir is not casting erythrocytic invading forms into the circulation.

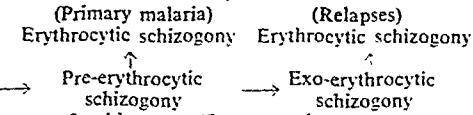
(*b*) *Natural Latency with Prolonged Incubation Period.*—This condition is well recognized in natural infections in Europe where in the early spring primary attacks may be caused by infections contracted in the previous summer and autumn. James (1931a) reported that 12 patients at Horton did not develop overt vivax malaria until six to ten months after they were bitten by infective mosquitoes (Madagascar strain). Swellengrebel and de Buck (1938) found that many of their patients infected with the local Dutch strain fell into this category, not developing overt malaria for some nine months after exposure to infective mosquitoes biting at any time of the year. There is a normal average incubation period of 21 days with the Dutch strain, and eight to nine months elapse between primary fever and the first relapse.

Shute (1946) produced good evidence that natural latency in vivax malaria—i.e., an overt attack in patients infected eight or nine months previously—was attributable to low sporozoite dosage; he suggested that relapses might be due to sporozoites which had been lying dormant in tissue cells, pointing out that they were able to survive for many months in the insect vector. According to Shute, natural latency occurs only when the sporozoites injected are too few to set up an immediate attack: about 2,000 sporozoites were regarded as the minimum necessary to establish infection by intravenous injection.

Serial subinoculations have not been performed on and after the ninth day following infection in these latent cases, but it seems likely that owing to a paucity of inoculated sporozoites only scanty pre-erythrocytic schizonts are produced; the resulting erythrocytic merozoites are evidently so few that non-specific phagocytosis in the liver, spleen, bone marrow, and blood—i.e., natural immunity—suffices to prevent the establishment of an effective parasitaemia. In consequence primary fever fails to develop, and with the Madagascar and Dutch strains an overt attack is not encountered for eight to nine months.

Comment.—Results based on infections with the New Guinea strain of *P. vivax*, which has a short-relapse pattern, support the view that latency is related to, and controlled by, the immunity response of the host as in cynomolgi malaria in monkeys.

In vivax infections with the St. Elizabeth, the Madagascar and the local Dutch strains, which are characterized by long-term latency before relapse, it is difficult to visualize how any immunity could have been acquired. In these circumstances the most likely explanation is a failure of erythrocytic merozoites to reach the blood stream and establish a parasitaemia, as Coatney and Cooper (1948) have pointed out. The failure to establish even a subpatent parasitaemia during this long-term latency is revealed by the negative results obtained with massive subinoculations in non-immunes. This might result from (1) cessation of exo-erythrocytic schizogony with the production of resting-stage parasites; (2) a slowing down of exo-erythrocytic schizogony and/or a decrease in the ratio of erythrocytic to liver-invading merozoites, so few of the former reaching the circulating blood that natural immunity suffices to prevent an effective parasitaemia developing; and (3) a switch-over to the exclusive production of liver-invading merozoites during exo-erythrocytic schizogony, the rate of which may or may not be retarded. It is suggested that No. 3 constitutes the most feasible working hypothesis, and that the atypical exo-erythrocytic schizogony which characterizes long-term latency is determined by the im-



biological qualities of the vivax strains under consideration. Latency ends when there is a reversion to normal exo-erythrocytic schizogony, with the production of the usual ratio of erythrocytic to liver-invading merozoites.

Once overt malaria supervenes after this long latent period it is interesting to note that several relapses not infrequently follow at monthly periods (close relapse pattern), indicating that normal exo-erythrocytic schizogony has been established and is being maintained.

B. Quartan Malaria (P. malariae)

In quartan malaria both sporogonous and erythrocytic schizogonous cycles proceed very slowly. Nothing is known of the tissue cycle. Unfortunately, subinoculations have not been performed during the incubation period, so no assessment can be made of the probable duration of the pre-erythrocytic cycle. The long latent periods, the presence of late relapses, and the difficulty of attaining radical cure suggest that exo-erythrocytic schizogony persists for many years. Blood-transfusion accidents, in which quartan malaria is transmitted by a donor who has been away from malarious areas for many years and been completely free from clinical attacks during this period, also support this view.

The following diagram depicts the tissue phases of the malaria parasite in monkeys infected with *P. cynomolgi*. It is suggested that the term "cynomolgi type" could usefully be employed in mammalian malaria for this type of schizogony. There is abundant indirect evidence that *P. vivax* follows the cynomolgi type of schizogony, and it seems highly probable that *P. malariae* does likewise.

Cynomolgi type of schizonogy (*P. cynomolgi, P. vivax*, and probably *P. malariae*)

C. Malignant Tertian Malaria (P. falciparum)

The present position in regard to the tissue phase of *P. falciparum* is much the same as that of *P. vivax* last year, before pre-erythrocytic forms had been discovered.

Pre-erythrocytic Cycle.—Subinoculation experiments reported by Fairley (1945) and Fairley *et al.* (1947) have shown that when donors are bitten by from 7 to 24 infective mosquitoes at a single session lasting 5 to 15 minutes sporozoites may gain access to the circulation during the time of biting or be detected at intervals up to 60 minutes after cessation of biting. Thereafter subinoculation results were uniformly negative until the seventh day, when they again became consistently positive. All of 41 subinoculations with 500 ml. of blood made from volunteers infected 6½ to 8½ days previously were positive.

The only reasonable interpretation of these findings is that, in falciparum as in vivax malaria, sporozoites inoculated into the tissues by infective anophelines rapidly gain access to the circulating blood and subsequently disappear rapidly from the circulation. Presumably they enter the parenchyma cells of the liver, where they develop into pre-erythrocytic schizonts, which liberate mature merozoites into the blood with extraordinary regularity on the seventh day of infection.

The causal prophylactic action of proguanil in malignant tertian malaria also suggests the existence of early tissue forms which are many times more sensitive to the drug than either sporozoites or merozoites. Fairley *et al.* (1946) found that a single dose of 50 mg. given between the 39th and the 131st hour following exposure to biting afforded complete protection; parasites never appeared in the blood and overt malaria failed to develop. Eight out of 10 volunteers receiving as little as one single dose of 10 mg. between 48 and 120 hours after infection were completely protected. It was found that proguanil (0.3 g.) given about the time of exposure to infection generally failed to protect; malaria could be prevented with certainty only if 1 g. of the drug was given. The conclusion reached was that proguanil had no action on the sporozoites as such, its lethal effect being due to small quantities persisting in the circulation and acting on tissue forms early in the pre-erythrocytic cycle. Later on the seventh day, by which time merozoites were entering the circulation, a single dose of 0.3 g. failed to give protection, though it was effective up to 144 hours. The most reasonable explanation of these experimental findings is that proguanil has a highly selective action on the pre-erythrocytic forms in falciparum malaria.

Exo-erythrocytic Cycle.—Though indirect evidence favouring a pre-erythrocytic stage is entirely convincing in malignant tertian malaria, the same cannot be said in regard to the existence of later exo-erythrocytic forms. None of the evidence advanced as indicating a persistent phase in vivax malaria is forthcoming for falciparum malaria. Thus in falciparum malaria (1) long latent periods are absent and recrudescences occur separated by only two to three weeks of apyrexia; (2) once the blood has been completely cleared of falciparum parasites by schizonticidal drugs like quinine, mepacrine, or chloroquine radical cure has been achieved: (3) it is useless to resort to the 8-amino-quinolines for radical cure as in benign tertian malaria: drugs of this group, though they are effective in preventing malignant tertian malaria when they are given in full dosage during the first six days of infection, are quite ineffective in the treatment of the acute attack and the eradication of the infection; this is because they are very poor schizonticides for *P. falciparum*; and (4) sporozoite-transmitted malaria is just as rapidly and radically cured by schizonticidal drugs as is trophozoite-transmitted malaria; this is contrary to the findings in benign tertian malaria.

To explain these therapeutic results it would be necessary to assume that, while the hypothetical exo-erythrocytic forms in falciparum malaria are just as susceptible to schizonticidal drugs as are asexual erythrocytic parasites, they are insusceptible to the 8-amino-quinolines. This would be exactly the reverse of the action of these drugs in benign tertian malaria. In toxic dosage the 8-amino-quinolines are known to have a true causal prophylactic effect in malignant tertian malaria, where their action on pre-erythrocytic forms is much more potent than in vivax malaria. Why, then, should they have no effect on exo-erythrocytic forms in malignant tertian malaria while destroying the exo-erythrocytic forms in benign tertian malaria?

All available data indicate that in malignant tertian malaria, after the pre-erythrocytic schizonts have ruptured and discharged their merozoites into the circulation on the seventh, and possibly the eighth and ninth days as well, the pre-erythrocytic schizonts disappear entirely without giving rise to later exo-erythrocytic forms. The subsequent course of the disease will thus be determined solely by erythrocytic schizogony, and if the parasitaemia be eradicated radical cure results.

It is suggested that the following diagram adequately depicts the tissue phase of schizogony as it occurs in malignant tertian malaria in man:

(Primary fever and recrudescences)
↑
Erythrocytic schizogony
↑
Sporozoite——→Pre-erythrocytic schizogony

Comment and Conclusions

At the beginning of the present century the life cycle of the malaria parasite in man appeared to be completely known. It is a matter of considerable interest that, nearly half a century later, hiatuses in precise knowledge of the subject still exist. Despite the brilliant work of Shortt and his colleagues, only the pre-erythrocytic stage in *P. vivax* has so far been demonstrated in man. The technical difficulties associated with the production of hyperinfection in man and the demonstration of tissue schizonts in the liver have been overcome. No suitable laboratory animal is known which can be experimentally infected with any of the human species of malaria parasite, and in these circumstances the various problems concerning tissue forms are unlikely to be solved finally without the use of experimentally infected volunteers.

In the meantime the following tentative conclusions based mainly on indirect evidence are put forward regarding the tissue phase of the three species of malaria plasmodia commonly affecting man.

1. In benign tertian and quartan malaria there are both pre-erythrocytic and exo-erythrocytic stages of schizogony similar to those now known to occur in cynomolgi malaria in monkeys.

2. In vivax malaria characterized by short-term relapses such as are produced by the New Guinea or Chisson strains, normal exo-erythrocytic schizogony is maintained throughout the whole course of the disease and erythrocytic merozoites reach the circulating blood with regularity. Relapses cease when solid immunity and tolerance have developed or radical cure has been established.

3. In vivax infections characterized by long-term latency before relapse, such as is seen in infections with the St. Elizabeth, Madagascar, and Dutch strains, parasitaemia and immunity fail to become established during this initial latent period. As a working hypothesis it is suggested that during latency the exo-erythrocytic cycle is atypical, inasmuch as schizogony is switched over to the exclusive production of liver-invading merozoites, so that no erythrocytic merozoites reach the circulation. Latency ends when there is a reversion to normal exo-erythrocytic schizogony; this is indicated by the close relapse pattern which supervenes after the long period of latency has terminated in an overt malaria attack.

4. In malignant tertian malaria, after the pre-erythrocytic schizonts have ruptured and discharged their erythrocytic merozoites into the circulation on the seventh and possibly the eighth and ninth days as well, they disappear without giving rise to late exo-erythrocytic forms. The subsequent course of the disease will be determined solely by erythrocytic schizogony, and if parasitaemia is eradicated radical cure will result.

CLINICAL VALUE OF PREGNANEDIOL ASSAYS*

BY

G. I. M. SWYER, M.A., D.M., D.Phil., M.R.C.P.

Endocrinologist, University College Hospital Medical School, London

A laboratory technique such as pregnanediol assay may lay claim to clinical value if it can be shown that its results yield information about diagnosis, prognosis, or treatment which will supplement that gained by unaided clinical examination. In assessing the clinical value of a given technique various factors must be considered and given due weight. The accuracy of the method, for example, is not of primary importance, though its ability to give unequivocal answers to the clinical questions posed is clearly a first requirement. Ease and speed of performance are significant considerations, and the nature and quantity of the clinical specimens required deserve attention. If to these we add the uniqueness of the information yielded by the technique, it should be possible to form an opinion of its value to the clinician in comparison with other laboratory procedures. In this paper the attempt is made to evaluate the position of pregnanediol assay, as judged by the above criteria and using the data that I have myself obtained.

A large number of different procedures for the assay of urinary pregnanediol have been described, some undoubtedly being far more accurate than others. I shall not attempt a comparative discussion of these rival methods, but certain general remarks are warranted. In the first place, methods requiring three or four days and many man-hours to complete are of little potential clinical value, no matter what their excellence as purely research techniques may be. Secondly, since by the nature of the clinical problems concerned repeated assays may be necessary, it becomes a matter of urgency to avoid, if at all possible, urine-collection requirements which would limit the application to in-patients only.

*Paper read at the British Congress of Obstetrics and Gynaecology, London, on July 6, 1949.

Clearly, few out-patients would co-operate to the extent of producing a weekly or fortnightly 24-hour urine collection, while the completeness of such collections as might be forthcoming would always be open to grave doubt. Great practical advantage would therefore be derived from the possibility of using first morning urine specimens rather than 24-hour collections, and it seemed reasonable to investigate such a possibility even though the variations in the results so obtained would be expected to be larger than those from 24-hour collections. With few exceptions, therefore, first morning specimens have been the rule throughout this investigation.

A final remark under this general heading may be made concerning the disadvantage, for clinical use, of methods which determine sodium pregnanediol glucuronidate, as compared with those which determine free pregnanediol. Any bacterial contamination may lead to hydrolysis of the glucuronidate and so give a spurious low value for the assay, and since in the hurly-burly of clinical medicine such contamination would be difficult to control, it seems wiser to avoid this potential cause of inaccuracy and to employ methods the results of which would not be vitiated in this way.

Considerations such as those outlined above led to the adoption, first of a modification of the Guterman (1944) technique (method I), and later of that described by Sommerville, Marrian, and Kellar (1948) (method II) after it had been shown (Swyer, 1949, wherein the details of the modification of the Guterman technique are described) that the method of Sommerville *et al.* was by almost all criteria the more preferable. Using these methods, an attempt has been made to study the clinical value of pregnanediol assay from the following points of view: (1) as a diagnostic test for pregnancy; (2) as a prognostic test in threatened abortion; (3) as a prognostic test for the likelihood of the initiation of labour by induction procedures; and (4) as a diagnostic aid in complications of pregnancy.

1. General Consideration of Results

For the purposes of this communication the results of a total of 858 pregnanediol assays are available for consideration. The details of these are set out in Table I, and the distribution of the values obtained is shown in the form of histograms in Fig. 1. The most striking feature of the latter is the considerable degree of overlap of values for pregnant and non-pregnant urines as obtained by both methods. The mode is shifted to the right in the case of method II, but apparently more so for pregnant than for non-pregnant urines. This is what would have been expected from the observations previously reported (Swyer, 1949), and is borne out by comparison of the two methods as pregnancy diagnosis tests (recorded below). The point which may be stressed is that, judging from the results as a whole, it cannot be expected that differentiation between pregnant and non-pregnant urines on the basis of their pregnanediol content will always be possible, so that the results in section 2 may be regarded as a fair sample of the overall results.

TABLE I.—*Broad Details of 858 Pregnanediol Assays*

Method	No. of Assays Performed		Totals
	Non-pregnant	Pregnant	
Modified Guterman	146	456	602
Sommerville, Marrian, and Kellar	49	207	256
Totals	195	663	858

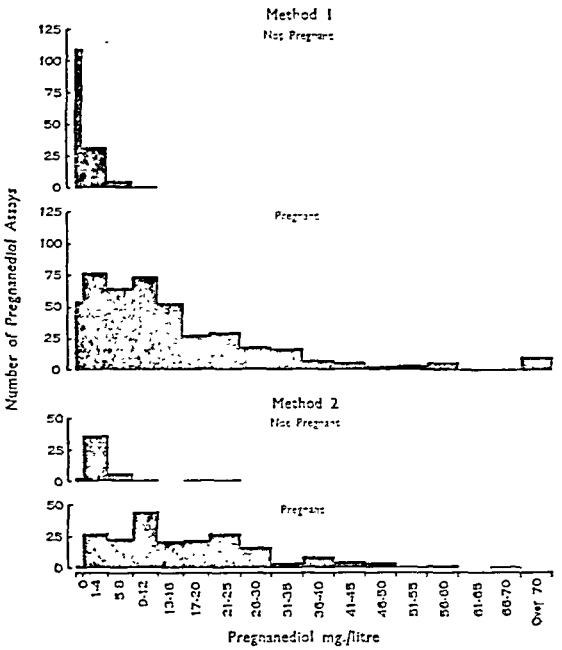

FIG. 1.—The distribution of 858 urinary pregnanediol assays.

2. Pregnanediol Assay as a Diagnostic Test for Pregnancy

The utilization of urinary pregnanediol assay as a basis for the diagnosis of pregnancy was first proposed by Guterman (1944, 1945), for which purpose he devised his rapid technique, which he did not, however, claim to be more than semi-quantitative. The high degree of accuracy for pregnancy diagnosis which Guterman found has not been uniformly achieved by other investigators (see discussion), and it was because of this that it was felt that yet another series might be desirable, especially one in which some other pregnancy diagnosis test of generally accepted validity was performed concomitantly with the pregnanediol assay on the same specimen of urine. For this purpose the Friedman test was selected, a standard quantity of 10 ml. of filtered urine being injected intravenously followed 48 hours later by sacrifice of the rabbit and examination of the ovaries for corpora lutea. All the specimens used in this series were actually sent for pregnancy diagnosis, so that in all cases there was some degree of clinical uncertainty. The subsequent fate of each was checked, and only those cases in which it was ascertainable have been included in the series.

For the first group of patients the modified Guterman procedure was used in 110 cases, and the results compared with the Friedman test are shown in Table II. In deciding whether the pregnanediol value was indicative of pregnancy or not, some level had to be chosen rather arbitrarily as the dividing-line. As a guide, assays were performed on the urines from 30 patients known to be non-pregnant, and

TABLE II.—*Concomitant Friedman Tests and Pregnanediol Assays (Method I) on 110 Urines Sent for Pregnancy Diagnosis (6 mg./litre Regarded as Minimal Value for Pregnancy)*

	Total	Friedman Test		Pregnanediol (Method I)	
		Correct	Incorrect	Correct	Incorrect
Pregnant ..	63	57 (90·5%)	6	26 (41%)	37
Non-pregnant ..	47	43 (91·5%)	4	44 (94%)	3
Totals ..	110	100 (91%)	10	70 (63·5%)	40

since the highest value found was 5 mg./litre, it was decided to regard 6 mg./litre as the minimal level for the diagnosis of pregnancy. Objections to this procedure could be cited, and because Guterman regards the "positive" colour in his test to be given by about 4 mg./litre of pregnanediol, the results have been recalculated on the basis of 4 mg./litre being the minimal level for pregnancy diagnosis (Table III). There is a slight improvement, but it is not sufficient for escape from the conclusion that, while false positives in non-pregnancy are rare, false negative pregnanediol values in pregnancy are so frequent as to condemn the test as an aid to pregnancy diagnosis.

TABLE III.—*The Results of Pregnanediol Assays (Method I), Previously shown in Table II, Recomputed on the Basis of 4 mg./litre as Minimal Value for Pregnancy*

	Total	Pregnanediol (Method I)	
		Correct	Incorrect
Pregnant	63	31 (49%)	32
Non-pregnant	47	43 (91·5%)	4
Totals	110	74 (67·3%)	36

Attention may be drawn to some of the cases in which discrepant results were obtained. There were two cases of proved hydatidiform mole, in both of which the Friedman test was positive (even when diluted 1/100, only 0.1 ml. of urine being injected); for the purposes of this comparison, these were interpreted as "false positive" Friedman tests, without any aspersions being cast upon the technical reliability of the test. In these cases the pregnanediol excretion was *nil* and 1 mg./litre respectively. Two other cases were clinically suspected as being those of hydatidiform mole; in one, in which the Friedman test was positive (though not on dilution) and the pregnanediol excretion was *nil*, subsequent events showed the case to be that of normal pregnancy; in the other, in which the Friedman test was negative and the pregnanediol excretion also was *nil*, no evidence either of pregnancy or of hydatidiform mole was obtained when the uterine contents were examined.

A specimen from a pregnant woman, when the period was only three days overdue, gave a negative Friedman test and contained 3 mg. of pregnanediol per litre; eight days later the Friedman test was still negative but the pregnanediol content had risen to 6 mg./litre. In a case which was subsequently proved to be that of ectopic pregnancy the Friedman test was negative and the pregnanediol excretion 4 mg./litre. In two cases of missed abortion the Friedman test was positive and the pregnanediol excretion 9.5 and 5 mg./litre. In neither case was a foetus found on evacuating the uterus. In three other cases "false negative" Friedman tests were obtained in cases of pregnancy; these must be regarded as technical faults. The corresponding pregnanediol levels were *nil* in two cases and 15 mg./litre in the third.

For the second group of patients, the procedure of Sommerville *et al.* (method II) was used in 101 cases, and the results, compared with the corresponding Friedman tests, are shown in Table IV. Once again 6 mg./litre is taken as the lowest permissible value for a "positive" pregnancy diagnosis, and it can be seen that the overall pregnanediol test results are considerably improved (82% correct) as compared with those in the previous series (63.5 or 67.3% according to the criterion of a "positive" value); that the reliability in pregnant cases is much greater (82.5 compared with 41 or 49%); but that a considerably larger number of "false positives" has now been produced (18.25% compared with 6%).

TABLE IV.—*Concomitant Friedman Tests and Pregnanediol Assays (Method II) on 101 Urines Sent for Pregnancy Diagnosis*

	Total	Friedman Test		Pregnanediol Assay	
		Correct	Incorrect	Correct	Incorrect
Pregnant ..	63	62 (98·5%)	1	52 (82·5%)	11
Non-pregnant ..	38	37 (97·5%)	1	31 (81·75%)	7
Totals ..	101	99 (98%)	2	83 (82%)	18

In this series there were three cases of missed or incomplete abortion; the Friedman test was positive in one, the pregnanediol value being 1 mg./litre, and negative in the other two, in which the pregnanediol values were 6 and 18 mg./litre respectively. There were, in addition, two cases of threatened abortion in which the diagnosis of pregnancy was uncertain at the time of testing; in one the Friedman test was negative, the pregnanediol value being 8 mg./litre and the patient aborted; in the other the Friedman test was positive, the pregnanediol value being 19 mg./litre and the pregnancy continued. A case of salpingitis which was considered clinically to have been possibly that of ectopic pregnancy had a pregnanediol excretion of 24 mg./litre; the Friedman test was negative.

3. Pregnanediol Assay as a Prognostic Test in Threatened Abortion

There have been several reports of the relation between pregnanediol excretion in cases of threatened abortion and the fate of the pregnancy (e.g., Hamblen, Cuyler, and Baptist, 1942; Guterman, 1946; Bender, 1947, 1948). The present series of cases is small compared with those of some previous authors, but the numbers are nevertheless sufficient for conclusions to be drawn which are not altogether in agreement with earlier reports.

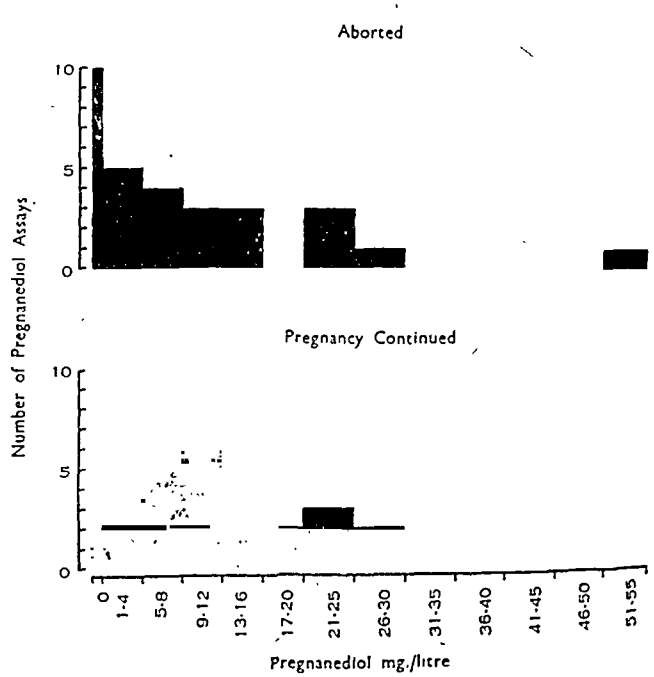

FIG. 2.—The distribution of 56 urinary pregnanediol assays from cases of threatened abortion.

Forty cases of threatened abortion have provided a total of 56 urine specimens for pregnanediol assay; the distribution of the values is shown in Fig. 2, where the cases are grouped into those that aborted and those that did not. The distributions are clearly different, but the overlap is

quite obvious. When the mean values for the two groups are compared by the t test, the following result is obtained:

Mean value for abortion group .. .. 8.733 mg./litre
" " " non-abortion group .. 12.4 "
n=54; t=2.579 (P<0.02>0.01)

It may therefore be concluded that the pregnanediol values in cases of threatened abortion are, in general, higher when the pregnancy is going to continue than when it is going to terminate, and that the chances of a difference between the means such as that observed occurring on a purely random sampling basis from a homogeneous population are more than 1 in 50 though less than 1 in 100 against.

The clinician, however, is more interested in individual cases than in the behaviour of patients with threatened abortion in general, and it is therefore of importance to consider the ability of the test to predict the outcome in individual cases. A pregnanediol value of 6 mg./litre has again been taken as the minimum for predicting continuation of the pregnancy, and the findings are set out in Table V, both on the basis of the first reading and, where more than one assay was performed, on the basis of the final assessment, a rising pregnanediol titre being taken as indicative of continuation of pregnancy. The correct prediction was given in 29 out of 40 cases in the final assessment (72.5%). Of the 40 cases, 57.5% aborted; of those that did not, 14 out of 17 had satisfactory or rising pregnanediol titres, but of the 23 patients who aborted, eight also had satisfactory pregnanediol titres.

TABLE V.—*Prediction of the Fate of Cases of Threatened Abortion on the Basis of Pregnanediol Excretion*

	First Reading			Final Assessment		
	Pregnancy Continued	Aborted	Total	Pregnancy Continued	Aborted	Total
Correct ..	12	14	26	14	15	29
Incorrect ..	5	9	14	3	8	11
Totals ..	17	23	40	17	23	40

4. Pregnanediol Assay as a Prognostic Test for the Likelihood of the Initiation of Labour by Induction Procedures

Since most observers agree that the spontaneous onset of labour is ordinarily preceded by a pronounced fall in the pregnanediol excretion, it seemed worth while to investigate the excretion in patients in whom, for various clinical reasons, it was desired to induce labour and to see what correlation, if any, existed between the amount of pregnanediol excreted and the effect of the induction procedure. This has been done in 10 patients, the results being shown in Table VI, in which the cases are recorded in ascending order of pregnanediol excretion.

TABLE VI.—*Pregnanediol Assays in Patients on whom Induction Procedures were Performed or Contemplated and the Results of Those Procedures*

Case No	Pregnanediol	Mode of Induction	Result
1	10·5 mg./24 hrs.	O.B.E.	Delivery
2	19·4 "	Spontaneous delivery	
3	23 mg./litre	High puncture	Delivery
4	25·2 mg./24 hrs.	O.B.E.	"
5	41 "	Spontaneous delivery	
6	49 "	O.B.E.	Delivery
7	49·7 "	O.B.E.	Nil
8	55·5 "	O.B.E.	Delivery
9	56 "	O.B.E.	Nil
		Repeated 2 days later	Delivery
10	57 "	Spontaneous delivery	

O.B.E. = Induction by castor oil, bath, and enema.

It is interesting to note that in three cases spontaneous labour began *before* the induction procedure was started, with pregnanediol excretions ranging from 19.4 to 57 mg. in the preceding 24 hours. On the other hand, the excretions in the two failures were both high—49.7 and 56 mg./24 hours respectively. It would seem, therefore, that, although induction is less likely to succeed at high levels of pregnanediol excretion, the prediction of the fate of a given case cannot be accurately made on the basis of pregnanediol assay.

5. Pregnanediol Assay as a Diagnostic Aid in Complications of Pregnancy

With a view to investigating the possible value of pregnanediol assay as a diagnostic aid in various complications of pregnancy 41 such assays were carried out on specimens obtained from 17 patients with various complications. The details are set out in Table VII, and the following comments seem justifiable: in cases of missed abortion variable values may be found, some "positive" and others "negative":

TABLE VII.—*Pregnanediol Assays in Various Complications of Pregnancy*

Case No.	Diagnosis	Pregnanediol mg./litre	Remarks
1	Missed abortion ..	9, 4, 3, 0	Friedman test positive. Curettage showed surviving placental tissue but no embryo
2	" " .	0, 5	Friedman test positive; no embryo found on curettage
3	" " ..	8	
4	" "	8	
5	? Incomplete abortion	10	Friedman positive, pregnancy continued
6	Hydatidiform mole ..	0	Confirmed by curettage
7	" "	0, 1	" "
8	? Hydatidiform mole	11	Friedman test positive undiluted only; normal pregnancy
9	" " "	0	" " "
10	" " "	0	Friedman test negative, non-pregnant
11	Ante-partum haemorrhage at 35 weeks	43, 38, 60, 23, 45	Daily pregnanediol assays, pregnancy went to term
12	Ante-partum haemorrhage at 37 weeks	60, 69, 51, 54, 16	" " "
13	Pyelitis at 29 weeks .	34	Pregnancy continued
14	Ectopic pregnancy ..	4	Friedman test negative, confirmed at laparotomy
15	Double uterus ..	33	
16	Polycystic ovary; punctured at 8 weeks	0, 5, 10, 31, 10, 9, 7, 9, 10	Daily pregnanediol assays; pregnancy continued
17	Dystocia dystrophia	92, 128, 78, 154	Daily pregnanediol assays at full term

the Friedman test may also be positive or negative, and it cannot be claimed that either test, or the two in combination, enables a definite diagnosis to be reached.

In both cases of proved hydatidiform mole the pregnanediol excretion was trivial, while chorionic gonadotropin was present in the usual large amounts. On the other hand, Case 8, clinically considered to be one of hydatidiform mole, was found to have both Friedman test and pregnanediol assay within the limits of normal pregnancy, and such it eventually proved to be. In Cases 9 and 10 hydatidiform mole was again suspected clinically; pregnanediol excretion was *nil* in both cases, but in one the Friedman test was positive undiluted only and normal pregnancy was the eventual conclusion, while in the other the Friedman test was negative and no further evidence of pregnancy was forthcoming.

The two cases of ante-partum haemorrhage showed pregnanediol excretions within normal limits for the periods of gestation, and the same applies to the case of pyelitis at the 29th week of gestation. In the case of ectopic pregnancy, both the Friedman test and the pregnanediol assay was misleading. The pregnanediol excretion in Case 16—that of polycystic ovary punctured at 8th week

of gestation—showed that the operation had not interfered with progesterone production and, accordingly, the pregnancy proceeded normally. In the last case—that of dystocia dystrophia—the pregnanediol excretion seemed to be excessive in view of the fact that labour, albeit of an ineffective type, had already begun.

Discussion

Before discussing the results reported above, it would seem desirable to point out why no mention has so far been made of the use of pregnanediol assay as a means of detecting ovulation in non-pregnant women. Sufficient studies have been made by various workers (e.g., Venning and Browne, 1937a, 1937b; Stover and Pratt, 1939; Hamblen, Cuyler, and Baptist, 1942, etc.) of the pregnanediol excretion during the luteal phase of the menstrual cycle to make it abundantly clear that the total excretion is so variable, and may be so small in apparently normal cycles, that only accurate techniques employed on complete collections of urine extending over several days (even the complete luteal phase) could hope to give indubitable evidence of corpus luteum activity. These requirements place the method entirely outside the realms of clinical practicability, and when it is granted that the basal body temperature record and the endometrial biopsy can give highly reliable results with very little effort, it must be conceded that pregnanediol assay can have no clinical value for this purpose.

The advantages claimed for pregnanediol assay as a diagnostic test for pregnancy were its rapidity (some three hours only are required for the Guterman method) and that it eliminates the inconvenience and expense of animal tests. The accuracy claimed by Guterman (1945) was 92.7% for 248 cases, the Friedman test in 201 of these being only 87.1% correct. Apart from McCormack (1946), who found complete agreement between pregnanediol assays and Friedman tests in 266 cases, no other observers seem to have achieved results at all comparable with these.

It is instructive to compare the published figures of the above authors with those of Reinhart and Barnes (1946) and Merivale (1948); this is done in Table VIII, which

TABLE VIII.—*Comparison of the Published Results of Various Authors with Pregnanediol Assay as a Pregnancy Diagnosis Test*

Author	No. of Patients	Percentage Accuracy	
		Pregnanediol Test	Friedman Test
Guterman	248	92·7	87·1
McCormack*	266	99·0	99·0
Reinhart and Barnes ..	130	69·2	—
Merivale	105	63·8	—
Swyer, Series I	110	67·5	91·0
" " II	101	82·0	98·0

* Omitting 30 cases of threatened abortion, all with negative pregnanediol and positive Friedman tests.

gives the overall accuracy figures. It is evident at once that there is close agreement between the results of Reinhart and Barnes, Merivale, and the first series reported in this communication, and gross disagreement of these findings with those of Guterman and of McCormack. Guterman (1945) has pointed out that his test should be restricted to patients with amenorrhoea who have not received progesterone therapy, but, as Reinhart and Barnes observe, the elimination of patients with vaginal bleeding or those who have received progesterone therapy materially limits the value of the test for routine clinical use.

Although in most of the published series the proportion of false positives is relatively low (that of Reinhart and Barnes is an exception), such results can be obtained in a variety of conditions—for example, the luteal phase of the menstrual cycle, which, if prolonged by a lengthened proliferative phase, might well lead to the clinical suspicion of pregnancy; corpus luteum cysts (Guterman, 1945; McCormack, 1946; Bender, 1948); arrhenoblastoma; a case of amenorrhoea with uterine enlargement due to metastatic carcinoma; and a case of salpingitis diagnosed clinically as ectopic pregnancy (Morrow and Benua, 1946). This last case is interesting in so far as it compares with a somewhat similar case reported in this paper, also with a "positive" pregnanediol excretion (24 mg./litre).

When all the available evidence is considered it seems impossible to escape the conclusion that the reliability of pregnanediol excretion is insufficient to warrant its use as a clinical method for pregnancy diagnosis. In its main claim, that of rapidity and convenience, it bears no comparison with the male-toad test, and, provided a supply of suitable animals can be assured, this test, or one of its modifications, would seem to fulfil all the requirements for clinical use.

Regarding the prediction of the fate of threatened abortion, once again the accuracy reported in the present series is far less than that claimed by Guterman (1946) (72.5% correct for 40 cases as compared with 93% for 73 cases). Bender (1948), however, has produced evidence that, using the Guterman test to differentiate cases of threatened abortion with high pregnanediol excretion from those with low outputs, and reserving treatment with progesterone for the latter only, a statistically significant increase in the salvage rate can be obtained; on the other hand, progesterone given to patients with threatened abortion with positive Guterman tests increased the likelihood of abortion. If this work can be substantiated, it would seem to be a really valid clinical application of pregnanediol assay. It is right, however, to point out that the administrative difficulty of obtaining the result of the test promptly, together with the necessity to wait for the first morning urine sample, may lead to delay in the exhibition of progesterone in those cases that warran it, the abortion perhaps becoming inevitable as a result.

In the diagnosis of complications of pregnancy, the result presented do not suggest that pregnanediol assays are likely to prove of much value except in the case of hyd[illegible] mole, in which pregna[illegible]iol seems to be [illegible] urine. It is true that [illegible]d be imp[illegible] generalize from the fi[illegible] two c[illegible] *point confirmatory sup[illegible]* sources: Guterman (19[illegible] cases of hydatidiform [illegible] reported the same results i[illegible] of seven cases, therefore, [illegible] suggest that absence of urin[illegible] clinically suspected as being h[illegible] a positive test for chorionic go[illegible] very substantially supports the dia[illegible] tion may be of great value at a[illegible] gestation, or in the case of multi[illegible] which conditions the gonadotrop[illegible] be so high as to give a positi[illegible] dilution.

If now the clinical value [illegible] pregnanediol assays from [illegible] abortion. from the evidence presen[illegible] laid down in the introdu[illegible]bortion have provided a tot[illegible]

*Since reading the proof[illegible]gnanediol assay; the distrib[illegible] case of hydatidiform mol[illegible] in Fig. 2, where the cases [illegible] dilution and absence of u[illegible] ever, has encountered tw[illegible]orted and those that did n[illegible] with "positive" pregnan[illegible]y different, but the overlap[illegible]

cluded that, in general, it has little to offer the practising clinician. It seems doubtful whether the relative inaccuracy of the methods suitable for clinical application can be held completely responsible for this state of affairs; rather should one ascribe it to the inherent variability of pregnanediol excretion both in the same and in different patients. Consideration of the factors responsible for this variability is beyond the scope of the present discussion, but it does seem permissible to observe that there are no solid grounds for believing that pregnanediol excretion reflects at all closely the progesterone levels of the blood, and undoubtedly the latter are of far the greater physiological significance. Simple direct means of assessing the blood progesterone would surely supply evidence of much more clinical value than could ever be expected from the pregnanediol excretion in the urine.

My sincere thanks are due to the members of the staff of the Obstetric Unit for their generous co-operation in these studies, and to Mr. A. A. Cernik for carrying out a large number of the assays, the results of which are recorded above.

VESICO-BULLOUS DISEASES AFFECTING THE EYE*

BY

ALICE CARLETON, M.D.

(*From the Department of Dermatology, Radcliffe Infirmary, Oxford*)

There are few skin diseases which may not at some time involve the eye and its appendages. It is impossible to consider all of them here, even in the most summary way. I propose instead to survey a single group—the vesico-bullous diseases of internal origin—affecting the skin and mucous membranes. Even with this restriction the survey must necessarily be a brief one.

The more one considers the vesico-bullous diseases the more one is struck not by their clinical differences but rather by their essential similarities. A common factor seems to operate in all of them, producing a particular type of cell reaction. It is this which makes a study of the group of special interest. In some diseases a virus, in others an unknown toxin, exercises a destructive action on the mucosae or on the deeper cells of the epidermis, with resultant cellular liquefaction. This seems to release a physico-chemical force, which in turn increases capillary permeability and attracts the filtrate as well as the local tissue fluid to the injured area. In this way a vesicle is formed. When the hydrostatic pressure within the vesicle has reached a certain point the movement of the fluid is checked. Whether the vesicle breaks down to form an oozing erosion or not depends largely on the thickness of its roof. Naturally, in the conjunctivae and other mucous membranes the covering is thin and the vesicles are correspondingly transient, so that the clinical picture is a raw oozing surface, whereas the skin may still show intact vesicles. But though the distribution and clinical appearance in the different diseases of this group are varied and characteristic, histologically we can distinguish only grades of severity in an essentially similar reaction.

Percival and Hannay (1949) have published an excellent study of the pathology of bullous formation, from which the following interesting sentence is taken: "To state the problem differently, it can be asked why the exudate remains in the dermis in urticaria, becomes localized at the dermo-epidermic junction in dermatitis herpetiformis, in the rete mucosum in eczema, and under the stratum corneum in pemphigus foliaceus, when the mechanism which made the exudate available is common to all four conditions, and is in all probability initiated by a common factor."

The diseases of this group which affect the eye are: herpes simplex; herpes zoster; erythema multiforme, including the severe form known as the Stevens–Johnson syndrome; foot-and-mouth disease; Touraine's aphthosis; dermatitis herpetiformis; and pemphigus. (Conjunctival scarring is associated with other skin diseases, such as bullous eruptions following vaccination, erythroderma ichthyosiforme of Brocq in its bullous form, epidermolysis bullosa dystrophica acquisita, and congenital syphilis, but these conditions do not belong to the group under consideration.)

Herpes Simplex

This well-known disease is characterized by the often-repeated occurrence of little groups of blisters on a base of oedema and redness. Its virus origin is amply proved, and corneal inoculation of a rabbit gives positive results. In contrast with what occurs in many virus diseases the host develops no immunity. On the contrary, a local hypersensitivity often causes the same small patch to respond on each occasion. The lips and face are most frequently affected, but lids, conjunctiva, or cornea may suffer instead.

The evidence suggests that the virus is a saprophyte living in happy matrimony with the tissues until a *tertium quid* disturbs the harmony. This may be any one of a variety of agents which include cold, heat, sunlight, food, drugs, and bodily upsets. The injured cell then goes through the processes of liquefaction and vesicle formation already described. Individual eruptions heal easily and need only to be kept clean. But to prevent recurrence is a difficult matter. Irradiation of the affected area of skin with *x* rays may produce an alteration which increases local immunity, or repeated inoculations with smallpox vaccine may raise the general resistance, but disappointing results are common.

Herpes Zoster

This complaint is not transmissible by inoculation. But as specific antibodies have been found in the blood, and inclusion bodies have been demonstrated in the vesicles, the evidence is in favour of a virus disease. The cutaneous reaction is greater and deeper than in herpes simplex. Haemorrhagic, purulent, or necrotic vesicles may occur and leave severe scarring. Many cases have been described as

*Read in the Section of Ophthalmology at the Annual Meeting of the British Medical Association, Harrogate, 1949.

sequelae of nerve infection or injury. So that here, again, it seems that a cell injury may open the door to a virus attack.

Herpes zoster is of special importance when it affects the eye, because of the risk of permanent injury. Becker (1948) has published a paper claiming good results in this condition by the injection of blood or serum from people who have recovered from the disease. This was for some time thought to be useless, because of statements such as that of Rivers (1939) that "convalescent blood or serum is of no value in the therapy of virus diseases, because by the time the disease is evident the organism has already penetrated the cell, a barrier which no antibody can transgress." Despite this view the method seems to give hopeful results. Becker used blood transfusions, blood plasma, and whole blood injections, with material taken from a donor any time from three weeks to two years after his having the disease.

Erythema Exudativum Multiforme

In 1866 Ferdinand Hebra described a disease affecting the face, the limbs, and sometimes the mucosae. The rash, as the name suggests, takes on many forms, such as macules, weals, bullae, or large annular or serpiginous plaques, of an angry blue-red colour. The eruption is short-lived but often recurrent. A somewhat similar rash, more rosy in colour and more varied in its distribution, can be elicited by a wide range of toxins. It is not clear whether Hebra's erythema multiforme is a specific entity or not. Ocular involvement generally takes the form of a pseudo-membranous conjunctivitis which may lead to shrinkage or uveitis. Lacrimation and photophobia are also seen, and corneal ulceration and perforation have been described. No causative agent has been found.

In 1922 Stevens and Johnson described a severe form of erythema multiforme which, in English-speaking countries, is now generally known under their name. An earlier account had, in fact, already been published by Rendu in 1916 under the name of "ectodermose érosive superficielle," and the condition is also referred to as "dermatostomatitis" or "eruptive fever with ophthalmia." This begins acutely with a rash like erythema multiforme, but the general symptoms are much more severe and the patient is feverish and looks gravely ill. The eyes, mouth, and genital mucosae are so inflamed and eroded as to be extremely tender, so that micturition becomes an ordeal and feeding may have to be done through a tube. Despite this disturbing start, improvement takes place in a week or ten days, and recovery is usual in about three weeks. Unfortunately, the eyes may be irreparably damaged. The conjunctivitis may leave adhesions or scars, or the corneal damage may end in opacities or in perforation. An effort should be made to keep the lids open with tiny strips of adhesive tape, but on account of the photophopia the patient is apt to struggle against this.

Patz (1947) made a study of six cases. He tried various methods of discovering a virus by making smears from the conjunctiva and vagina, by complement-fixation tests with psittacosis antigen, by cultures in chick embryos, and by the intracerebral and intraperitoneal injection of vesicular fluid into rabbits, guinea-pigs, and mice. All results were negative.

Vincent's stomatitis has been found associated with erythema multiforme in three cases, and it was suggested that the fuso-spirochaete, by altering tissue sensitivity, might lead to the Stevens–Johnson syndrome. But proof of this is not forthcoming, and the association of the two complaints has scarcely ever been found.

Anderson and his colleagues (1949) claim to have found a virus with cytoplasmic inclusion bodies following rabbit cornea inoculation. Their study was limited to one case.

Treatment is symptomatic. Nicotinic acid is said to be of use, but as most cases clear up spontaneously it is difficult to be sure of its value.

Foot-and-Mouth Disease ("Fièvre Aphtheuse")

This may be acquired by direct contact with infected animals or, less often, by drinking their milk. The distribution is not unlike the preceding condition, but the skin around the nails is chiefly affected and the lips and mouth are dry and burning, whereas in the Stevens-Johnson syndrome lesions are more often seen on the wrists and ankles, and there is profuse salivation. Ocular involvement is not common. If there is any difficulty in diagnosis, guinea-pig inoculation in foot-and-mouth disease gives a positive result.

Touraine's Aphthosis

There is a fearsome dermatological jungle in which various diseases with resounding eponymous titles struggle for life. They are the chronic erosive conditions affecting the eyes, mouth, and genitalia. Each specialist is naturally absorbed in his own field, which for him takes precedence of all others, and so a number of syndromes have arisen, such as Sutton's (1911) "periadenitis mucosae necrotica recurrens," Loblowitz's (1910) "ulcus neuroticum oris et vulvae," Lipschütz's (1923) "acute vulval ulcer," "pustulo-ulcerous balanitis," and others. Behcet (1937, 1940), a Turkish dermatologist, described a triple symptom-complex in which all three areas—eyes, mouth, and genitalia—are affected simultaneously or in sequence. Little round or oval ulcers with yellow sloughs succeed one another in the mouth, vulva, or glans penis, associated with inflammation of the cornea, conjunctivitis, or sclera. The skin has a tendency to develop acneiform pustules or deep-seated lesions of the erythema nodosum type.

In 1941 Touraine made an extensive study of this whole group. He suggests that the various conditions belong to one single systemic disease, which he ascribes to an ultra virus, and to which he gives the name "aphthosis." He thinks that this agent, like the virus of herpes simplex, becomes established in the body and manifests itself clinically when for divers reasons the individual becomes anergic. Touraine divides his aphthosis into three groups according to severity and extent.

1. A generalized form, affecting the skin, mucosae, and joints. This is severe and starts with fever and general systemic disturbance.

2. A milder form, involving the mouth and genitalia, with few scattered vesico-pustules on the skin.

3. Aphthosis of the mucosae alone, in the form of small recurrent ulcers, or, less often, a single large ulcerative area which may be mistaken for a venereal infection. There is much variety in the severity and duration of the ulcers, and also in the length of the free periods. Recurrences may be precipitated by any bodily upset, such as infectious fevers or pregnancy, or by local trauma or operative procedure.

Touraine's view is substantially in accord with Whitwell's (1934) conception of "embolic showers" causing necrotic apthae in mucosae and skin. It may be that future research will show the conception of "aphthosis" to have over-simplified the problem. But until further knowledge is obtained the harassed dermatologist can only feel relief at having so many odd sheep neatly penned into one fold.

Dermatitis Herpetiformis

It is unnecessary to dwell on the clinical appearance of this well-known disease, particularly as the eyes are rarely affected. Only a few points of special interest will be mentioned. There is a special sensitivity to iodine, and in one case involving the eyes and nasopharynx painting with iodotannic spirit produced a disastrous exacerbation. There is some evidence that hypersensitivity to a bacterial toxin may be an important aetiological factor. It is often possible to control the disease, and sometimes even to cure it, by long-continued small doses of sulphapyridine. The aim is to raise the resistance of the body rather than to eliminate the supposed toxin.

Pemphigus

The cause of pemphigus is unknown, and it follows that the validity of the different divisions or varieties is still uncertain. Dermatologists, however, clearly distinguish between four clinical types—acute pemphigus, chronic pemphigus or pemphigus vulgaris, pemphigus foliaceus, and pemphigus vegetans. Acute pemphigus is a fulminating disease generally occurring in people who handle animal carcasses. It begins on the hand and spreads over the whole body, leading rapidly to death in 80 to 90% of cases. In pemphigus vulgaris the development is more insidious, but, according to Lever and Talbott (1942), death occurs in 83% within one year of onset and in 97% within two years. It follows from these figures that treatment does no more than alleviate the symptoms. Grace and Hellman (1946), however, claim to have cured two cases of pemphigus vulgaris with blood transfusions from two patients who had recovered. One cannot generalize on the strength of two cases, but as spontaneous cure is rare this claim is of great interest.

A brief survey of the literature on ocular pemphigus reveals an almost inextricable confusion, and the term is manifestly used in the loosest way. One author talks of "ocular pemphigus" under one heading and "pemphigus vulgaris with ocular involvement" under another. A different prognosis and a different racial distribution are given, but no criteria for distinguishing one from the other. Klauder and Cowan (1942) have stated the issue clearly. They use the original term "essential shrinkage of the conjunctiva," and believe that this occurs in a number of dermatoses, of which some are very rare. The list includes: severe erythema multiforme or the Stevens–Johnson syndrome; bullous eruptions following vaccination; erythroderma ichthyosiforme of Brocq in its bullous form; dermatitis herpetiformis; epidermolysis bullosa dystrophica acquisita; and congenital syphilis.

Klauder and Cowan would confine the term "ocular pemphigus" to a benign affection of old age often associated with pemphigus of the nasopharynx and with a trivial bullous eruption of the skin, especially of the lids and face. The genitalia may also be involved. It is not found more often in Jew than in Gentile, though, as is well known, the Jewish race is particularly sensitive to pemphigus vulgaris. The question therefore remains to be answered, Is ocular pemphigus a special entity with a benign course, occurring late in life and with no particular racial distribution, or is it a mild form of pemphigus vulgaris, to which disease Jews are so sensitive that if affected at all they develop the severe form?

Discussion

A group of diseases exist which produce vesicles or bullae, breaking down into erosions of the skin or mucous membranes. Despite clinical differences the histopathology is essentially similar throughout the group. Some are caused by viruses; in some no virus origin can be discovered. A connecting thread seems to run through the group, as shown by a symmetry of distribution and a susceptibility to precipitating factors of many different kinds which alter the reactivity of the cell and lead to its liquefaction. Somewhere in this complexity we should be able to find the master key which would fit all the doors. It may be that this will be given to us by research in pure science, and, indeed, this seems already possible. Before the war Peters (1936), considering the biochemistry of the cell and the perpetual shuttle of its metabolic life, made an incidental note of the fact that very small quantities of arsenic could, as it were, stop a cell "breathing" by interfering with one of its enzyme systems—the pyruvate oxidase system, which is instrumental in breaking down glycogen or glucose into carbon dioxide and water. At the onset of war, when scientists were directed to problems of immediate practical importance, the Department of Biochemistry at Oxford, under the charge of Professor Peters, began to consider possible antidotes to arsenical poisoning in the form of lewisite. This earlier observation provided a starting-point for research, and in a short time Thompson (quoted by Carleton *et al.*, 1946) discovered that a dithiol—dimercaptopropanol—could combine with arsenic and even remove it from the cell, to be harmlessly excreted in the urine.

Now, acute arsenical dermatitis has features not unlike the diseases we have been considering. A drop of lewisite on the skin brings out a large bulla. In the conjunctiva it produces a penetrating destruction of the eye. In arsenical poisoning, such as may arise in the treatment of syphilis, bright-red blotches appear on the limbs and spread to a generalized exfoliative dermatitis. Interference with a single enzyme system can therefore cause cellular liquefaction and breakdown. A known poison acting in an understood manner produces results which are partly reversible by an antidote of known chemical composition. In the vesico-bullous diseases, we know neither the poison nor its precise manner of acting, still less the antidote. But we have here an excellent example of the fruitfulness of correlating clinical with purely scientific research in the solution of our joint problems.

RETINAL ARTERIAL OCCLUSION IN MIGRAINE

BY

G. S. GRAVESON, M.A., M.D., M.R.C.P.

Lecturer in Neurology, University of Manchester

(From the Department of Neurology, Manchester Royal Infirmary)

The occurrence of retinal arterial spasm in the early phases of attacks of migraine has occasionally been described. Unfortunately, an opportunity of examining the optic fundi at such times seldom presents itself, and therefore the frequency and distribution of arterial changes are unknown.

When retinal spasm is severe an occlusion of the affected vessel may occur, leading to a permanent defect in the field of vision. This is a rare complication, but one of much greater theoretical importance than its infrequency would suggest. Such cases supply direct evidence that the pre-headache phenomena of migraine are due to vasospasm. For this reason the following cases are worth recording.

Case 1

A girl aged 17 first attended hospital in April, 1948. From the age of 7 she has had periodic "bilious attacks" without headache. Her attacks of migraine began early in 1947 and have occurred at approximately monthly intervals. Until March, 1948, they were all similar in type, beginning with a whirling sensation surrounded by coloured lights and zigzag formations which started in both eyes simultaneously in the temporal half of the fields and spread to involve central vision. This teichopsia usually lasted about 10 minutes and disappeared suddenly, to be succeeded sometimes by a throbbing headache situated in the fronto-temporal region on both sides. The headache was equally short-lived, never lasting longer than about a quarter of an hour.

In March, 1948, she suddenly developed a blurring of vision in the right eye and thought that one of her usual attacks was starting. Instead the blur persisted and no headache followed. She noticed that the visual defect was present only in the right eye, and that it was situated below and to the left of whatever she looked at. It had remained unchanged for three weeks before her first visit to hospital.

Examination.—The only abnormalities to be found were in the right eye. Ophthalmoscopy revealed an occlusion of the superior temporal retinal artery at a point about half a disk diameter from where it crossed the disk margin. From this point the vessel continued as a fine thread from which no light reflex was seen. In the macular area just above the fovea there was a small area of retinal oedema. The disk itself was normal. The field of vision showed a hemianopic defect in the lower half-field, especially on the nasal side (Fig. 1). This did not involve the fixation point, so that her visual acuity remained normal: 6/5 J1. Her cardiovascular system was normal; the blood pressure was 130/85. Blood Wassermann reaction was negative. There was no family history of migraine.

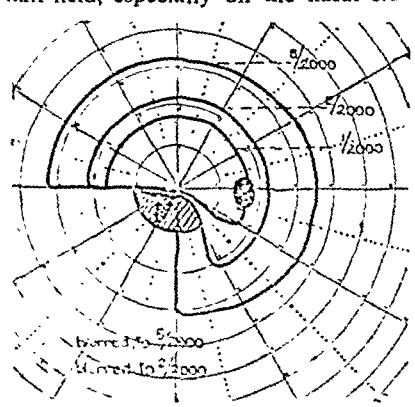

FIG. 1—Case 1. Field of vision of right eye, April, 1948: showing a defect in the lower half-field, particularly on the nasal side, together with a paracentral relative scotoma in this sector.

She was seen again in December, 1948. In the intervening nine months she had had eight further attacks of migraine—all consisting of headache preceded by scintillating scotoma formation in both visual fields. The defect in the right visual field had improved a little and was now confined to the inferior nasal quadrant (Fig. 2). Fundal examination still showed an occlusion of the superior temporal retinal artery, and the superior temporal portion of the optic nerve-head was now pathologically pale. The macular oedema had disappeared. Her visual acuity remained 6/5 J1 in the right eye.

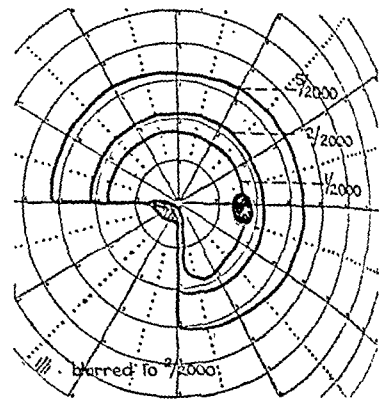

FIG. 2.—Case 1. Field of vision right eye, December, 1948: showing improvement in both the sector defect and the relative scotoma.

Case 2

A woman aged 35 was first seen in October, 1948, complaining of impaired vision in the right eye. For the previous two years she had suffered from attacks of migraine at approximately monthly intervals. These attacks would start with a scintillating scotoma in the right homonymous fields of vision, which lasted for about 10 minutes and was then followed by a bifrontal headache. This was never very severe and lasted no longer than half an hour. Only once or twice had vomiting occurred in the attacks.

In June, 1948, she had two attacks of teichopsia—flashes, spots, zigzag formations—in the right eye only. The first lasted 10 minutes, the second half an hour, but neither attack was followed by headache.

On September 21 at 11 a.m. she suddenly developed a dazzling sensation with spots and flashes of light all over the right visual field. Within a minute a patch of blackness appeared in the upper nasal quadrant of the right field. The dazzling sensation lasted until 4 p.m. and then disappeared, but the blackness remained and obscured vision in this quadrant. No headache followed the attack. She was first seen a month after this episode. In the interval there had been no subjective change in the visual defect in the right eye.

Examination.—Abnormalities were confined to the right eye. In the fundus the retinal arteries were all quite distinctly thinner than in the left eye. The inferior temporal vessel was particularly narrowed, being threadlike in appearance and showing no light reflex. The retinal veins were normal. The disk itself was normal, except for the inferior temporal sector, which was paler than the rest. The retina adjacent to the disk at this point was slightly swollen and blood-streaked. Visual acuity: 6/6 J1 right and left. The right field of vision (Fig. 3) showed a defect in the upper nasal quadrant extending a little into the upper temporal quadrant and corresponding to the occlusion of the inferior temporal artery. The cardiovascular system was normal, and the blood pressure 135/80. The blood Wassermann reaction was negative.

She was seen again two months later, in December. She had had no further attacks of migraine. The right field of vision had improved a little, though she was still blind in the upper nasal quadrant. The fundal appearances were unchanged, except that the retinal oedema had now disappeared.

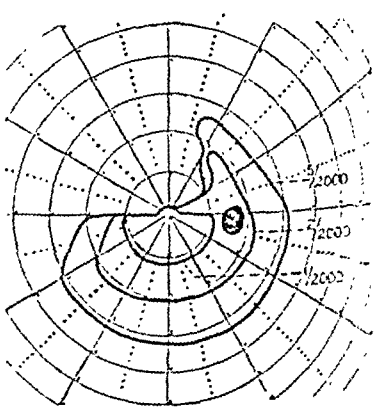

FIG. 3.—Case 2. Field of vision right eye, October, 1948: showing a defect in the upper nasal quadrant and the adjoining part of the upper temporal quadrant.

Case 3

A woman aged 31 was first seen in 1942, when she was 24 years of age. Three years previously, while washing her face one morning, she suddenly lost the sight of her right eye. There was no accompanying headache or ocular pain. For three or four hours the blindness was complete, and then vision returned in the upper half of the field, so that she was left with an inferior altitudinal hemianopia. She was then otherwise symptom-free for about six months. Thereafter, however, she began to suffer from attacks of blurring of vision in the remaining superior half-field associated with ocular pain. These attacks have occurred at intervals of about three months ever since. They begin with a sudden stab of pain over the right eye, which is followed by a sharp pain in the eyeball lasting several minutes. At the same time vision in the lower half-field becomes blurred and remains so for about three hours. There is no family history of migraine.

Examination.—In 1942 the only abnormalities were in the right eye. The field of vision showed an incomplete inferior altitudinal hemianopia with macular sparing (Fig. 4). The superior temporal and nasal retinal arteries were much smaller than the inferior vessels in this eye. In 1948 there was no change in the field defect in the right eye or in the calibre of the affected vessels. Her right disk showed an optic atrophy limited to the superior half of the nerve-head. Visual acuity was 6/5 J1 in the right eye. Neurological examination was otherwise normal. Her blood pressure was 110/75, and the heart and peripheral arteries were normal. The blood Wassermann reaction was negative.

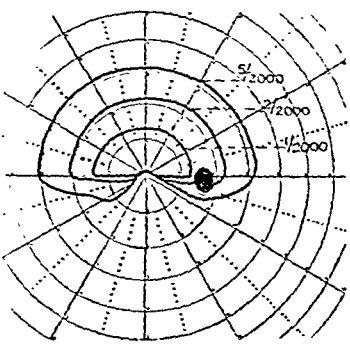

FIG. 4.—Case 3. Field of vision right eye, March, 1942: showing an inferior altitudinal hemianopia.

Case 4

A girl aged 16 was first seen in May, 1948. Between two and three years previously she had had two or three attacks of sudden transient blurring of vision in the left eye, each lasting no longer than a minute and not followed by headache. Then in June, 1946, she developed an influenza-like illness with coryza, generalized aches and pains, malaise, and fever. She went to bed, and after two days felt normal again. On the third day, while lying in bed on her right side, she suddenly saw "black clots" in the left field of vision. Within seconds she became blind in the eye except for a little blurred vision in a small central area (imperfect macular vision). No headache followed this attack of blindness, which has since persisted unchanged.

A year later she began to experience right-sided headaches. She would get pain of a throbbing type over the right brow which came on quite abruptly and lasted up to 20 minutes. At first the headaches were frequent—several times a week—and came on whenever she did a good deal of close work—e.g., reading or sewing. Latterly she had avoided these activities, with a corresponding reduction in the number of her attacks.

On two occasions, in August and September, 1947, she had attacks of scintillating scotoma in the right eye. In the first she suddenly developed a bright dazzling light covering the centre of the right field of vision. After a few minutes this broke up and expanded peripherally, leaving the centre clear, and finally disappeared from the periphery after about 10 minutes. No headache followed. The second attack was very similar but of shorter duration, and again was not followed by headache. There is no family history of migraine.

Examination.—Vision in the left eye was reduced to 6/36 J18. The optic disk was small and atrophic. The retinal arteries were all thin and did not reflect light. The macular area was normal in appearance. The changes were those of an occlusion of the central artery of the retina. The left field of vision was restricted to a small area around the fixation point (tubular vision). The left pupil did not react to direct light, whilst the right pupil failed to react consensually. The right eye was otherwise normal—visual acuity 6/5 J1. There were no other neurological abnormalities, and the cardiovascular system was normal. Her blood pressure was 135/85. The blood Wassermann reaction was negative.

Discussion

The evidence available from both clinical and experimental observation suggests that the symptoms of migraine result from alterations in the calibre of blood vessels in the head, and that both intracranial and extracranial vessels take part in this process. In a fully developed attack two stages are recognized: (1) the stage of pre-headache symptoms—e.g., visual disturbances, paraesthesiae, asphasia—which are thought to be due to functional disturbances of cortical cells secondary to the anoxaemia produced by intracranial angiospasm; and (2) the stage of headache produced by an excessive dilatation, particularly of extracranial arteries, which stimulates the pain nerve endings accompanying these vessels.

Although a vascular theory of migraine was first propounded as long ago as 1870 by du Bois Raymond, it is only in the last decade or so that adequate proof of its occurrence has been obtained. This has been largely due to the work of Wolff and his collaborators, excellently summarized in a recent publication (Wolff, 1948). Their experiments have shown quite clearly that the intensity of the migraine headache is proportional to the degree of dilatation of extracranial arteries, and that the relief from headache achieved by drugs such as ergotamine tartrate is directly related to the degree of vasoconstriction produced.

Whilst the mechanism of headache production is now no longer in doubt, evidence that the prodromal symptoms are the result of intracranial vasospasm has largely been indirect. There are numerous records of patients who have been left with a permanent homonymous visual-field defect after a migrainous attack. A recent case has been described by Rich (1948), and references to previous cases are given in his article. It has been assumed that in such patients arterial spasm has been so intense as to lead to thrombosis and subsequent cerebral softening. Where pathological proof is lacking, however, criticism may be made that such defects may be caused by an underlying vascular abnormality—e.g., an aneurysm or angioma—and that the migraine is of a "symptomatic" rather than a "primary" type. An instructive example of this is mentioned by Kinnier Wilson (1940)—that of a man of 45, a "life-long martyr to migraine," who for 20 years had had a fixed homonymous quadrantanopia, ultimately proved to be caused by a blood-vessel tumour. Adie (1930) described eight cases of permanent hemianopia following migraine attacks. Seven occurred in men—an unusually high proportion for primary migraine. One had had an attack of subarachnoid haemorrhage, which strongly suggests the existence of a structural vascular abnormality.

Evidence of the existence of vasospasm has been accumulated in other ways. James (1945) has shown that a vasodilator drug (carbachol), given regularly, is effective in reducing the frequency of attacks. Wolff in one case was able to show that the inhalation of amyl nitrite, in sufficiently low concentration to produce vasodilatation without a fall in blood pressure, would cause the disappearance of a scintillating scotoma, whereas the latter increased in size when the concentration was great enough to produce hypotension.

That these vascular changes probably produce their effects on the cerebral cortex is shown by the electroencephalographic findings of Engel, Ferris, and Romano (1945). They found that the development of hemianopic teichopsia was accompanied by alterations in the wave pattern from the posterior part of the contralateral hemisphere. In five cases examined during the initial phase of an attack slow irregular 5–7 c/s waves were recorded whilst the visual phenomena lasted and for a brief period afterwards.

Proof of the occurrence of vasospasm in the early stages of a migraine attack is therefore largely circumstantial. The occasional development of retinal arterial occlusion, however, offers more direct and visible evidence, for it seems altogether probable that such thrombosis is secondary to spasm of the affected vessel. Very few such cases have been published.

Galezowski (1882) was probably the first to record such an occurrence. He described four patients afflicted with migraine in each of whom uniocular loss of vision had occurred in relation to attacks of headache. In two, thrombosis of the central artery of the retina was found, one developed an occlusion of the superior branch, whilst the fourth showed peripheral retinal arterial thrombosis with fundal haemorrhages. Their ages ranged from 15 to 67.

Löhlein (1922) described the case of a man who had suffered from attacks of migraine since the age of 20. At the age of 37 he had a nocturnal attack of headache and vomiting; the following morning there was blindness in the left eye. Vision was reduced to the recognition of hand movements in a small peripheral portion of the field and showed no subsequent improvement. Optic atrophy developed, and the condition was considered to be due to a haemorrhage into the optic nerve. Five years later, at the age of 42, a similar attack was followed by blindness in the right eye due to extensive retinal and vitreous haemorrhage, vision later improving. At the age of 46 another attack occurred, reported by Wegner (1926), which resulted in complete blindness and total optic atrophy in the right eye. It seems probable that an occlusion of the central artery of the retina, secondary to vasospasm, was the underlying mechanism of these attacks. Retinal haemorrhage in migraine has also been recorded by Brasch and Levinsohn (1898) and by Vallery-Radot *et al.* (1937), and was seen to a slight extent in Case 2.

Hunt (1915) reported the case of a woman of 31 who had suffered from attacks of migraine since childhood. After a nocturnal attack she noticed a blurring of vision in the right eye and on examination was found to have a central scotoma and some oedema of the nerve-head. These changes regressed and after a period of two months central vision had returned to normal, although a slight pallor of the disk was present. Hunt described the condition as a retrobulbar neuritis and visualized the cause as a vascular lesion in the optic nerve.

The best-documented case is that of Grönvall (1938). His patient was a girl who had begun to suffer from attacks of scotomata and, occasionally, giddiness followed by headache, at the age of 12. At the age of 18 she developed a sudden giddiness associated with a sensation of spots before the eyes. Within a few minutes she became totally blind in the right eye. After a further ten minutes vision returned to the lower half-field of vision, but the upper half remained greyish-black. When examined the following day there was an area of retinal oedema between the disk and the macula; the inferior temporal retinal artery was occluded, and perimetry revealed a defect in the upper nasal quadrant and an adjoining portion of the upper temporal quadrant of the field of vision. The oedema subsided after a month and the field defect showed a slight improvement, but the arterial occlusion remained permanent.

Walsh (1947) records brief details of several patients who suffered from transient attacks of unilateral and bilateral blindness which were sometimes followed by migrainous headaches. One patient developed permanent occlusion of the central artery of the retina in an attack occurring four days after parturition.

Finally, Grimsdale (1940) has written an interesting description of his own personal experience of an attack of retinal arterial spasm, which resulted in an occlusion of a branch of the superior temporal vessel.

Of these nine recorded cases of retinal arterial obstruction in migraine four have occurred in the central artery of the retina, giving rise to severe uniocular blindness; four occurred in peripheral branches, producing sector field defects; and one (Hunt's case) developed a central scotoma, possibly the result of an occlusion of an intraneural branch of the central retinal artery. In the four cases recorded here, one has involved the central retinal artery and three its peripheral branches.

No age group seems particularly predisposed to these complications; there is certainly no evidence that increasing age and coincident arteriosclerotic changes render the migrainous subject liable to such sequelae, for they have affected young and old alike. In the cases described here there were no signs of local retinal or generalized arterial disease, nor was there evidence of any possible source of emboli. Cases 1 and 2 suffered from attacks of migraine before the onset of the retinal occlusion, whilst in Cases 3 and 4 the occlusion was apparently the first symptom of the disease.

Migraine should therefore be considered as a possible cause of those cases of retinal occlusion, occasionally experienced in practice, in which no cardiovascular disease can be found. The condition is probably less uncommon than its recorded occurrence might suggest. Three of the four cases here described have been seen within a period of 12 months. Their interest lies chiefly in the fact that they provide further evidence that the symptoms of migraine are the result of vasomotor disturbances in the territory of cranial blood vessels.

Summary

Four cases of retinal arterial occlusion occurring in migraine are reported. In one case the central artery of the retina was affected; in three cases occlusion occurred in a single peripheral branch.

Such cases provide evidence for the theory that the pre-headache phenomena of migraine are due to vasospasm.

I wish to thank Dr. F. R. Ferguson for his permission to publish the records of cases under his care.

STUDIES IN PRIMARY PLEURISY WITH EFFUSION*

BY

BRIAN C. THOMPSON, M.D.

(From the Tuberculosis Service, Otago Hospital Board, New Zealand)

This paper is on the subject of primary pleurisy with effusion and is not concerned with effusions arising in patients with established pulmonary tuberculosis. The pathogenesis of such cases is not difficult to imagine, though it is a curious fact that so many occur in patients with old-standing, often calcified, and apparently inactive pulmonary lesions, and that the prognosis is remarkably good (Thompson, 1947a). These can properly be called "secondary" tuberculous pleural effusions. The fluid which may form in the course of artificial-pneumothorax treatment is perhaps a special case in this group.

The "primary" effusion of my definition formed the subject of a previous investigation in which 190 cases were studied over a period of years, with follow-up results which were virtually complete, including regular routine radiography of the chest (Thompson, 1946, 1947b). Although by definition coexisting or preceding pulmonary tuberculosis was not present in this earlier series of cases, radiographs sometimes revealed lesions within the thorax that were typical of the tuberculous primary complex of Ghon. These lesions were characterized by enlargement of the hilar lymph glands, or by parenchymal infiltration, or by both together, sometimes including evidence of bronchial stenosis or atelectasis of a broncho-pulmonary segment. Where a parenchymal lesion was apparently alone, this was of the primary-infection type in which the glandular component could reasonably be regarded as radiologically invisible. These intrathoracic lesions were known sometimes to have preceded the pleural effusion; in no case did the effusion come first. In some cases the effusion occurred on the same side as the pulmo-glandular complex; in others it occurred on the opposite side.

Follow-up showed that 25% of all cases developed tuberculosis within five years. The earliest evidence of this subsequent disease often occurred within a few months, soon enough to indicate that it was directly associated with the preceding pleural effusion, and that it was not, for example, a further tuberculous infection from an outside source. In nearly one-half of the cases of subsequent tuberculosis, this became evident within the first year of observation. Two-thirds of the remainder occurred within the second year. None occurred later than the fifth year. The incidence, course, and prognosis of the subsequent tuberculosis was not apparently related to the age of the patient or his social state, or to such clinical conditions as the magnitude of the effusion, the degree of toxaemia, or the presence of demonstrable intrathoracic primary lesions. Nor, contrary to the opinion of Trudeau (1939), was there evidence that any treatment, or absence of treatment, of the original condition influenced the ultimate course of the disease.

Since the publication of the above studies, opportunity has arisen for observing the development of pleurisy with effusion from its earliest beginnings in persons already under observation, especially among nurses and medical students at Dunedin Hospital, who undergo regular tuberculin testing and *x*-ray examination as part of their routine medical care. The following selected case histories are presented as clinical illustrations of some of the factors involved.

*Paper read at a meeting of the Royal Australasian College of Physicians in Dunedin on September 8, 1948.

Case Reports

Case 1.—A student nurse aged 28 was negative to intradermal injection of tuberculin P.P.D. first and second strength on entry in March, 1946, and again in June. At her next routine examination in January, 1947, she gave a 4-plus reaction to P.P.D. first strength, and a radiograph showed involvement of the left lung and tracheo-bronchial glands typical of primary tuberculosis. Though well and without symptoms, she had evidently incurred a recent primary infection, probably a few weeks previously, when she had complained of a transient malaise and sore throat, but without reporting sick. After a month's leave at home she returned to duty. In July an acute left pleurisy with effusion supervened.

Comment.—This is a case of typical primary tuberculous infection in a previously uninfected adult with an intrathoracic primary complex, followed by pleural effusion on the same side six months later. Such an interval is regarded as about the average duration between the entry of tubercle bacilli and the development of pleurisy, but there are wide variations. Delay for a longer period is easily explained by the traditional latency of tuberculosis. The shortest period I have seen was in Case 2.

Case 2.—A student nurse aged 19 was negative to both strengths of P.P.D. on entry in September, 1945, and again in June, 1946. Sixteen weeks later she developed an acute left-sided pleurisy with lymphocytic effusion. Three weeks after that an effusion also occurred on the right side.

Comment.—A pleural effusion occurred four months after a negative tuberculin test and therefore not more than 10 weeks from the latest possible date of conversion to tuberculin-positivity, according to the accepted incubation period of about six weeks following primary infection (Wallgren, 1945). The subsequent contralateral pleurisy also occurred with unusual rapidity, and with no indication of its causation. The patient made an uneventful recovery and eventually returned to duty.

Case 3.—A nurse aged 18 on entry in 1942 was Mantoux-negative at that time and was repeatedly negative up to January, 1946, when she was found to be negative to the first strength of P.P.D. but positive to the second strength. The chest radiograph was clear. In September, 1946, she developed cough and pain in the left side. A pleural friction-rub was heard in the left axilla, corresponding to *x*-ray evidence of a pulmonary lesion of primary type, and the E.S.R. was 18 mm. Four months later a pleural effusion occurred on the opposite side.

Comment.—Pleural effusion developed contralateral to a primary tuberculous pulmonary lesion, over which dry pleurisy had been noted but which had not led to the formation of fluid. As in Case 3 there was nothing to suggest a haematogenous spread of disease. The passage of infection from the left to the right hemithorax could, however, have been by way of the mediastinal lymph glands.

Case 4.—A student nurse aged 23 was Mantoux-negative on entry in 1944. In January, 1946, she was still negative to both strengths of P.P.D., but 12 weeks later the sites of both these intradermal injections became acutely inflamed. A radiograph showed enlargement of glands in the left hilum (Fig. 1). She developed an irritative cough towards the end of the year, and in March, 1947, was found to have an accumulation of fluid between the upper and lower lobes of the left lung (Fig. 2), which was aspirated and replaced by air. Though no pulmonary lesion could be seen, she had a productive cough with tubercle bacilli in the sputum, and in view of a localized wheezing

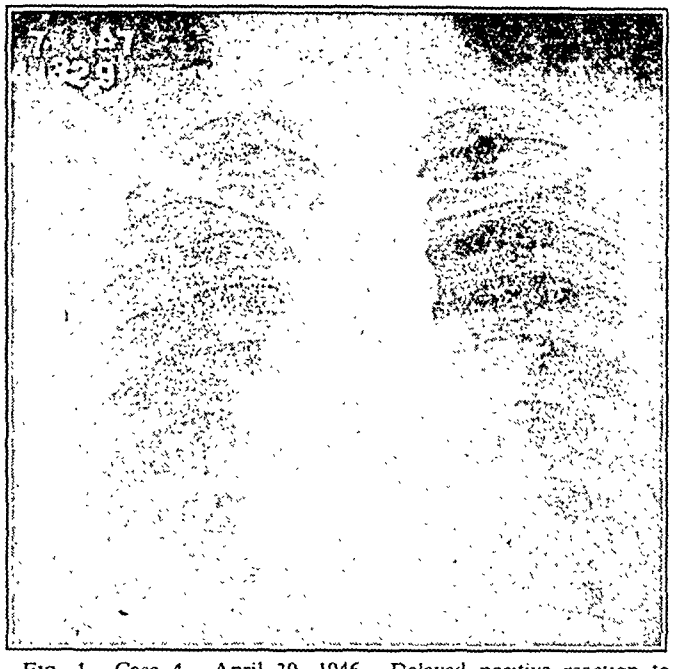

Fig. 1.—Case 4. April 30, 1946. Delayed positive reaction to Mantoux tests done 12 weeks previously. Left pleural effusion occurred 10 months later.

respiration it was suspected that the caseous gland mass had broken through into the bronchial tract. This was confirmed by bronchoscopy, which revealed an ulcerated area on the anterior aspect of the left main bronchus, just proximal to its upper division. After prolonged sanatorium treatment, during which she became entirely free from symptoms and from recoverable tubercle bacilli, she developed an acute pleural effusion on the right side, just 24 months from first becoming tuberculin-sensitive.

Comment.—The phenomenon of delayed reaction to tuberculin retained in the skin through the period of primary infection (Daniels, 1943) enables the date of that infection to be fixed very exactly. This nurse must have received her first dose of tubercle bacilli in the second

Fig. 2.—Case 4. March 8, 1947. Lateral view showing fluid lying in the interlobar fissure.

fortnight of February, 1946, her left-sided effusion appearing 12 months later, with persistence of the glandular component of the primary complex throughout that period. It may be significant that the fluid spread from the hilum in the interlobar fissure without extending widely over the costal surface, which it was quite free to do, as the subsequent artificial pneumothorax showed (Fig. 3). The mass of caseous glands radiologically seen at the hilum were found to press on and to erode the adjacent bronchus. It is reasonable to suppose that these same glands could similarly involve the pleural sac, lying as they do against its hilar reflection, and that extension to other lymph glands in the mediastinum could reach the opposite pleura, producing there the later effusion.

Case 5.—A medical student aged 22 was Mantoux-negative up to his final year, when he incurred a brief febrile illness with cough and chest pain. A radiograph showed a left-sided primary tuberculous complex. Ten months later an effu-

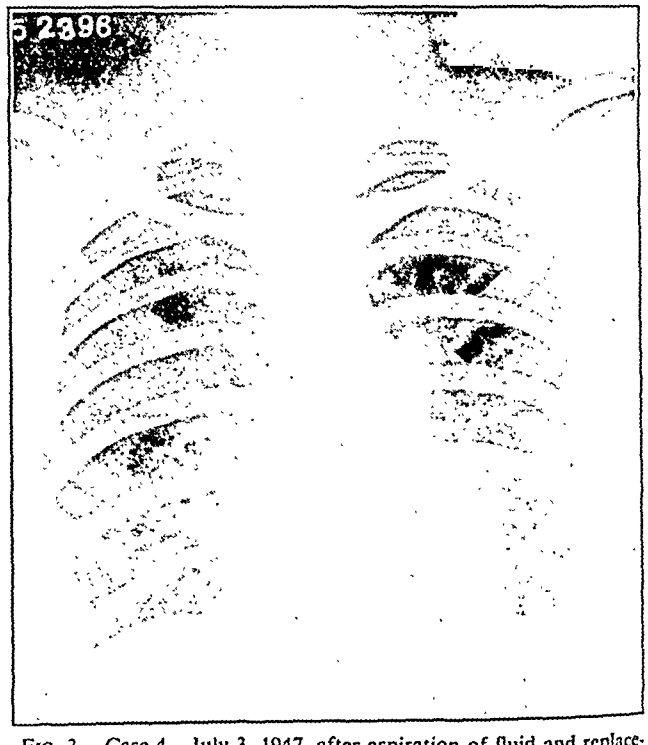

Fig. 3.—Case 4. July 3, 1947, after aspiration of fluid and replacement by air. A free pneumothorax is present, with some displacement of the heart to the right.

sion developed on the same side, associated with very severe toxic disturbance. Despite repeated aspiration the fluid always re-formed rapidly. His temperature remained high and he gradually declined into an almost typhoid state. Impaired percussion and bronchial breathing were found to the right of the sternum, and a small effusion eventually formed in the right pleural cavity. The clinical picture and *x*-ray appearances suggested the presence of so large a caseous gland mass as to constitute a tuberculous mediastinitis, with pressure atelectasis of the right lung base. After air-replacement of the left-sided effusion, a thoracoscope was introduced. There were no tubercles to be seen, but the pleura was intensely pink, and fine filamentous adhesions, easily separable, were forming between the upper lobe of the lung and the parietal pleura. Parenteral streptomycin was begun, 0.5 g. twice daily, with immediate and dramatic results. Within two days his temperature fell to normal, his appetite returned, apathy abated, and recovery steadily advanced to convalescence.

Comment.—The pleural effusion followed a primary tuberculous complex on the same side, and spread to the other side apparently by way of the mediastinum. Miliary

disease was excluded by thoracoscopy. Striking features were the unusual degree of toxaemia, so great that a fatal issue looked likely, and the prompt response to streptomycin.

Case 6.—A woman doctor aged 24 was Mantoux-negative throughout her training, and up to December, 1947, when for some weeks she experienced vague malaise, culminating in an outbreak of erythema nodosum. A radiograph showed a lesion in the right upper lung field typical of primary tuberculosis. On strict rest in bed her temperature fell from 100° F. (37.8° C.) to normal and her E.S.R. from 25 to 6 mm., and her general condition rapidly improved. Her only symptom occurred 16 weeks from the onset of the skin eruption—a transient pain beneath the right scapula aggravated by deep inspiration. There were no physical signs, but a radiograph showed a slight peripheral spread of the earlier lung lesion, with definite pleural reaction.

Comment.—The primary infection was marked by the occurrence of erythema nodosum. Pleurisy ensued on the same side as the primary lesion, clearly as a result of local spread from its pulmonary component. There was no constitutional upset and no rise of temperature, while the E.S.R. remained well within normal limits during this latter episode.

Case 7.—A schoolgirl aged 15 was examined as a contact of her father, who had recently died from acute pulmonary tuberculosis. She was found to have an active primary complex on the right, with contiguous bronchopneumonic spread from the focus in the lower lobe. This localized extension increased under conditions of strict rest in bed, and eight weeks later a right pleural effusion supervened. Thereafter she showed steady clinical improvement and was discharged from sanatorium 12 months later, in excellent condition, to live quietly on the family farm. Within a month there appeared below the left clavicle a new infiltration which spread slowly, to become arrested and show signs of regression only after 18 months of observation. Throughout this period, from the initial resolution of her effusion, she was entirely without symptoms, gained weight, and had a normal unchanging sedimentation rate. There was, however, radiological evidence of the glandular component of the primary complex persisting right up to the development of the subclavicular infiltration and resolving only when the latter reached apparent stability.

Comment.—This case is a further example of pleural effusion following a recent primary complex, which remained incompletely resolved during medical treatment and gave only radiological evidence of its existence, and subsequently led to pulmonary tuberculosis on the opposite side.

Discussion

These cases have been chosen for the light they throw on the pathogenesis of pleural effusion. All had undergone a recent primary tuberculous infection and were under close observation before and after that event. In six of the seven cases a primary complex within the thorax was seen to develop which was radiologically visible throughout the pleurisy in five. Case 7 is an example of the development of subsequent pulmonary tuberculosis, and the primary complex continued to be visible by radiograph.

One way in which the pleura may be invaded from the primary complex is illustrated by Cases 6 and 7, in which direct spread from the pulmonary focus was observed. Another way is shown in Cases 3, 4, and 5, in which there was strong evidence that the lymphatic gland component eroded the pleura near its mediastinal reflection. The opposite pleura was subsequently affected in three cases (Nos. 2, 4, and 5), indicating that so-called bilateral effusions are due probably to spread from adjacent lymph glands.

The latent period between primary infection and exudative pleurisy may be as short as 16 weeks (Case 2) but is usually between 6 and 12 months. Persistence of evidence of an active primary complex should lead one to expect pleurisy in any case of recent tuberculous infection. The term "primary" pleurisy with effusion is therefore used definitively, to make clear this association, though in a strict pathological sense it doubtless belongs to the indeterminate post-primary phase. More distinctly post-primary is the relatively uncommon pleural effusion, usually bilateral, which may accompany generalized haematogenous dissemination from the primary complex, with miliary tuberculosis throughout the lungs, extrapulmonary lesions, and even polyserositis.

It seems that caseous lymph glands behave in the mediastinum in a manner similar to that often observed in the neck, as Erwin (1944) has suggested, by breaking through the boundary of least resistance. This may be the wall of a bronchus, clinically not uncommon, as in Case 4. It is reasonable to suppose that the contiguous pleura may be invaded in the same way, though Burke (1940) has advanced the possibility of retrograde spread by way of the subpleural lymphatics. Tubercle bacilli can nearly always be grown from the exudate by careful technique (Close, 1946), and one cannot doubt that they are directly concerned.

All these cases were in young adults. Pleurisy with effusion does of course occur in children, but very infrequently compared with the large number of primary tuberculous infections that occur during childhood (Hardy and Kendig, 1945). As children also do not tend to develop progressive pulmonary tuberculosis, it may be supposed that they are better able to resist such infections before puberty than after puberty, and to arrest the primary lesion usually at a stage short of pleural involvement.

This study offers no further evidence on the pathogenesis of subsequent tuberculosis. Case 7 illustrates the close succession of events—from primary lesion, through exudative pleurisy, to pulmonary infiltration—and the likelihood that the whole process is largely beyond the influence of our present therapeutic means.

Conclusions

Primary pleurisy with effusion is an incident in the natural history of tuberculosis. It arises by direct pleural involvement from either the pulmonary or the glandular component of an active intrathoracic primary complex, incurred as a rule a few months previously. Specially susceptible to this condition are adolescents and young adults who, having escaped the tubercle bacillus earlier in life, meet it for the first time by casual contact, usually outside the home.

The subsequent course is probably not different from that seen in other forms of late primary infection, with a marked tendency to pass into a stage of chronic pulmonary or extrapulmonary tuberculosis. Such progression may be entirely subclinical and may take place irrespective of or even during medical treatment.

The pleural effusion is to be regarded less as a disease in itself than as significant of persistent and dangerous primary tuberculosis.

AETIOLOGY OF ERYTHEMA NODOSUM IN CHILDREN

BY

S. A. DOXIADIS, M.D.

Lecturer in Child Health, University of Sheffield

Erythema nodosum is considered by most authors to be a non-specific manifestation of hypersensitivity to various allergens, mainly bacterial (Collis, 1933; Rötnes, 1936; Spink, 1937; Wallgren, 1938a; Ernberg and Gabinus, 1939; Perry, 1944; Skiöld, 1945; Löfgren, 1946), although some still consider it to be a specific infectious disease (Miescher, 1948).

Of the infective agents responsible for the hypersensitivity, *Mycobacterium tuberculosis* is the commonest in childhood. Second in frequency is the streptococcus, the aetiological significance of which has been demonstrated by Collis (1932). Very few cases in childhood are due to hypersensitivity to other organisms. An exception to this is found in the parts of the U.S.A. where coccidioidomycosis is common, for about 11% of the children with this infection have an eruption similar to erythema nodosum (Smith *et al.*, 1946).

The relation of erythema nodosum to tuberculosis in children was noticed as long ago as 1872 (Uffelmann, 1872) but little attention was given to it until Ernberg (1921) published his theory and observations on the nature of this relation. The opinion that erythema nodosum is commonly a manifestation of primary tuberculous infection became accepted more generally as a result of the work of Wallgren (1927, 1928, 1930, 1931). Of 800 children with erythema nodosum whom he had seen by 1938 (Wallgren, 1938a) 95% had a positive tuberculin reaction. Reports on the tuberculin reaction of children with erythema nodosum have been published by many authors on the Continent (Göbel, 1933; Moro, 1934; Landorf, 1935; Debré *et al.*, 1938; Mallet, 1938; Nobécourt and Briskas, 1941; and many others).

Although it is known (Wallgren, 1938a) that the incidence of tuberculous infection in children with erythema nodosum varies from country to country, studies in the British Isles (Boganovitch, 1930; Begg, 1932; Collis, 1933; Forman and Whitwell, 1934; Thompson, 1939; Gray, 1945) and North America (Dickey, 1932; Brandon *et al.*, 1938; Lincoln *et al.*, 1944; Roddy, 1949) have been based on small series of cases only. The single exception is the study by Perry (1944), who determined the incidence of tuberculosis in 112 patients with erythema nodosum. Sixty-seven were children—in 29 (43.3%) the eruption was definitely related to tuberculosis, in 21 (31.3%) the relation was probable, and in 17 (25.4%) tuberculous infection was excluded.

The present paper concerns 100 children with erythema nodosum. It is presented because of the small number of similar observations in this country and in order to draw the attention of family doctors once more to the importance of recognizing erythema nodosum in children as a valuable sign of tuberculous infection.

Material

All the 100 children were seen and investigated in the Children's Department of the Royal Victoria Infirmary, Newcastle-upon-Tyne, or at the Children's Hospital, Sheffield. Seventy were seen by the author and the information for the remaining 30 was obtained from their case notes. In 20 children a course of sulphonamides preceded the eruption by a period varying from 12 hours to 12 days. These children are included in the present series, as it is considered (Löfgren, 1945; Doxiadis and McLean, 1948) that erythema nodosum occurring after the administration of sulphonamides is fundamentally the same as that in which the eruption is spontaneous.

The age and sex incidence is shown in Table I. The low incidence after the age of 13 is without significance because older children receive treatment in other departments.

TABLE I.—*Age and Sex Incidence of Erythema Nodosum*

Age, Years Completed	No. of Children	Age, Years Completed	No. of Children
1	6	8	7
2	5	9	11
3	6	10	13
4	5	11	7
5	4	12	10
6	6	13	11
7	7	14	2

Boys 38. Girls 62.

The seasonal incidence is presented in Table II, and it can be seen that there is a smaller number of cases in summer and autumn.

TABLE II.—*Seasonal Incidence of Erythema Nodosum*

Month	No. of Children	Month	No. of Children
January	12	July	3
February	10	August	6
March	10	September	5
April	9	October	6
May	11	November	10
June	5	December	13

Results

All children were tested with tuberculin. The first test was either the application of tuberculin jelly on the skin or the intradermal injection of 0.01 mg. or less (0.005–0.01 mg.) of old tuberculin. If the test was positive no further tests were performed. If the reaction was negative then larger amounts of old tuberculin (0.1–1 mg.) were injected intradermally.

A positive reaction to tuberculin was found in 88 children (88%). In three of these the first test was negative or doubtful and all three showed a strongly positive reaction to 0.1 mg. of tuberculin. Of the 12 tuberculin-negative children, four were tested with 0.1 mg. and eight with 1 mg or more of old tuberculin.

Of the 88 tuberculin-positive children, 59 (67%) had other evidence of active tuberculous infection. In 54 the radiograph showed marked undoubted unilateral enlargement of the hilar shadows, and in some of these there were opacities in the lung, on the same side as the hilar enlargement, consistent with the diagnosis of primary tuberculosis. Five children had cervical adenitis and in three the pus obtained by incision or aspiration contained *Myco. tuberculosis*.

Within three months after the appearance of erythema nodosum a pleural effusion developed in four of those children, there was an extension of the radiological signs in the lungs in two, miliary tuberculosis developed in one, and one child died from tuberculous meningitis.

Of the remaining 29 tuberculin-positive children, there were no radiological changes in 22, and doubtful changes in seven.

The relation of tuberculous infection to erythema nodosum is summarized in Table III. No further investi-

gations were made in the 12 tuberculin-negative children. The eruption followed a sore throat in five of them and scarlet fever in one.

In none of the 100 children was there any evidence of rheumatic infection, and in the 80 who were observed for at least six months after the eruption there has been no sign of involvement of the heart.

Discussion

The high incidence (88%) of positive tuberculin reactions in the 100 children with erythema nodosum is comparable to the incidence found by many Continental workers and is even higher than that in the only other recent series from this country (Perry, 1944).

It cannot be stated with certainty that the erythema nodosum was due to tuberculosis in all the 88 tuberculin-positive children. It may be said, however, that at least in the 59 (67%) who at the time of the eruption had other evidence of active tuberculous infection there was a close relation between the eruption and the infection. In the remaining 29 children (33%) the same relation probably existed.

These results show that in this country, too, most of the children with erythema nodosum are passing through their primary tuberculous infection. Any child therefore with erythema nodosum should be considered to have been recently infected with tuberculosis unless carefully performed tuberculin tests are negative. Because of the high degree of sensitivity to tuberculin of the tuberculin-positive children with erythema nodosum a jelly test is usually sufficient to elicit a positive reaction. If intradermal tests are used, the amount of old tuberculin in the first injection should never exceed 0.01 mg.

Special investigations were not made in the 12 tuberculin-negative children, and there is therefore no direct evidence that a streptococcal infection was the main aetiological factor, though a sore throat or scarlet fever preceded the eruption in six.

The absence of any demonstrable relation between erythema nodosum and rheumatic fever in the present series is worthy of emphasis. Some doctors still consider that erythema nodosum is "rheumatic" in origin and fail therefore to carry out any further investigations. Out of 800 children with erythema nodosum Wallgren (1938b) saw only one in whom the eruption was related to rheumatic fever. Löfgren (1946), in his study of 184 cases of erythema nodosum in adults, found that there was no evidence that erythema nodosum is connected with rheumatic fever; and Skiöld found a probable connexion in only five (1.4%) out of 354 adults with erythema nodosum. It is clear, therefore, that erythema nodosum is very rarely due to rheumatic fever.

Summary

Out of 100 children with erythema nodosum 88 had positive tuberculin reactions. In 59 of these there was an active primary tuberculous lesion. In the remaining 29 tuberculosis was probably the aetiological factor. In none of the children was there any connexion between erythema nodosum and rheumatic fever.

I wish to thank Professor J. C. Spence, Professor E. J. Wayne, and Dr. T. Colver for their permission to make use of their cases, Professor R. S. Illingworth for his valuable advice, and Dr. D. Stone for his assistance. Part of the material was collected during the tenure of a Luccock Research Fellowship at the Medical School, King's College, University of Durham.

POST-OPERATIVE THROMBOSIS*

INVESTIGATION OF A PROPOSED TEST FOR ITS PREDICTION

BY

G. W. VAUSE GREIG, M.B., F.R.C.S.

Surgical Registrar, the General Infirmary, Leeds

In a paper on intravascular thrombosis Cummine and Lyons (1948) claimed that by the examination of the post-operative coagulation time and estimation of the plasma fibrinogen-B they could foretell the onset of impending thrombosis. They further suggested that if the coagulation time as measured by the capillary tube method drops to four minutes, and if fibrinogen-B (an intermediate product in the change of fibrinogen into fibrin) can be demonstrated in the blood, then prophylactic anticoagulant therapy should be instituted.

In spite of the introduction of heparin and dicoumarol, thrombosis and embolism still contribute to the incidence of post-operative morbidity and mortality, and a simple test to determine which patients should be given anti-coagulant drugs to prevent these complications is being widely sought. Investigation of a series of cases, using the proposed tests of Cummine and Lyons, was therefore undertaken.

*Being the subject of a short paper delivered before the Surgical Travellers Club at Leeds on January 21, 1949.

Method

It was decided to measure the coagulation time before operation and then daily after operation, but the fibrinogen-B test, which entails a venepuncture, was done pre-operatively, the day after operation, and then subsequently only when there was a fall in the coagulation time.

This regime was followed in 43 cases, and in a further eight acute cases the estimations were started the day after operation. All the patients investigated had undergone a major operation varying from a partial gastrectomy to a prostatectomy. Of the 51 patients 29 were over 55 years of age; only six were under 40, and of these one was a case of cholelithiasis for which a cholecystectomy had been performed, three had had partial gastrectomies for chronic duodenal ulceration, and one (the youngest of the series, aged 32) had had an abdomino-perineal resection for carcinoma of the rectum. Thus all were in the groups in which post-operative thrombosis is most common.

The estimations were discontinued when the patient was ambulant, as it was considered that by that time the danger of spontaneous intravascular clotting has generally passed. That this belief is erroneous was proved by the one case in the series which developed a thrombosis.

Results

The results may be divided into four groups.

Group 1.—In 12 cases the coagulation time throughout was above four minutes and no fibrinogen-B was found in their blood post-operatively (Fig. 1).

Group 2.—Ten patients had fibrinogen-B in their blood post-operatively, but their coagulation time remained higher than four minutes (Fig. 2).

Group 3.—Eleven cases showed a lowering of the coagulation time to four minutes or less but had no fibrinogen-B in their blood at the time of this fall (Fig. 3).

Group 4.—In 18 cases there was a fall of the coagulation time to four minutes or less associated with the finding of fibrinogen-B in the blood.

According to Cummine and Lyons there is no danger of thrombosis in the first three groups, and none of the cases in these groups showed clinical signs suggesting it.

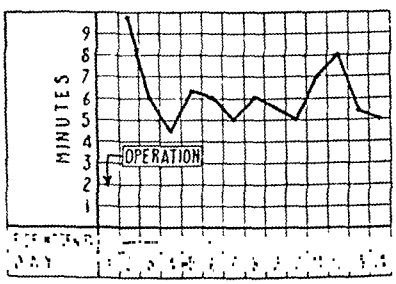

Fig. 1.—Graph of case typical of Group 1 (woman aged 76; gallstone ileus). Coagulation time remaining above four minutes. No fibrinogen-B.

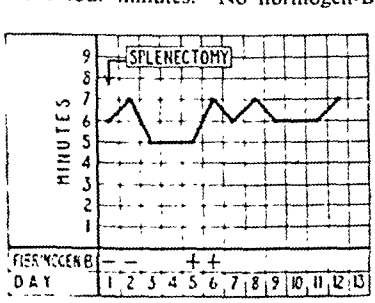

Fig. 2.—Graph of case typical of Group 2 (woman aged 51; portal hypertension). Fibrogen-B present, but no lowering of coagulation time.

The cases in Group 4, comprising more than one-third of the whole series, satisfied the criteria laid down by Cummine and Lyons for the prophylactic administration of heparin and dicoumarol. The first two cases showing this fall in coagulation time coincident with a positive fibrinogen-B test were given heparin and dicoumarol, and in both, as was to be expected, the result was a marked prolongation of the clotting time, but in one the plasma fibrinogen-B persisted (Fig. 4). However, as these two cases occurred among the first five investigated, and as they displayed no evidence of thrombosis, it was decided to withhold anticoagulant drugs until the tests had been more certainly evaluated.

Out of the subsequent 16 cases in Group 4 only one developed a thrombosis, and this took place after the patient was ambulant and the daily coagulation time determination had been discontinued (Fig. 5): the day after the thrombosis her coagulation time was within normal limits and her blood free from fibrinogen-B. This woman, who had a deep femoral thrombosis, was not treated with heparin or dicoumarol, but was kept ambulant, with a firm crêpe bandage from toes to groin. She suffered no embolic phenomena or further spread of the thrombosis, and when seen three months later had only a slight residual swelling of the leg in the ankle region, with no incapacity.

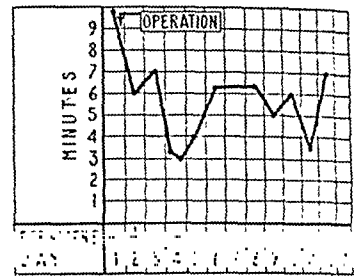

Fig. 3.—Graph of case typical of Group 3 (man aged 58; carcinoma of rectum). Lowering of coagulation time to below four minutes, but not associated with fibrinogen-B in the blood.

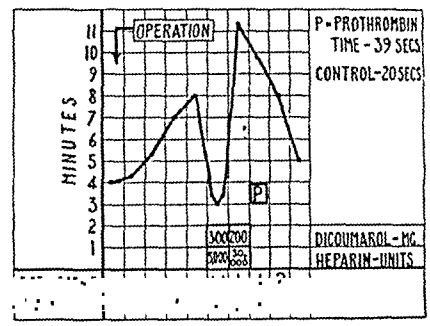

Fig. 4.—Graph of case typical of Group 4 (man aged 57; for duodenal ulcer). ow four minutes togeth in the blood.

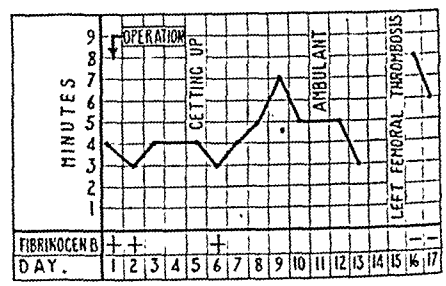

Fig. 5.—Carcinoma of caecum in a woman aged 64. The only case in Group 4 showing clinical signs of thrombosis—occurring after patient was fully ambulant.

Discussion

As this investigation progressed disappointment was felt because these proposed tests did not enable us to predict accurately the cases which would develop post-operative thrombosis: it is obviously not practicable to treat 35% of patients with heparin and dicoumarol. However, one point of interest did arise. This was that of the 43 cases examined both before and after operation 34 showed a fall in the coagulation time in the first twenty-four hours after operation and 21 of these had a fall to four minutes or less. Ten patients whose clotting times were measured at the end of operation before they left the operating theatre all showed a marked increase in rate of coagulation. These results suggest that what Bergquist (1940) called "the pre-thrombotic state" is not infrequently present within the first few hours after operation or even earlier, during operation, and this is the danger time when thrombosis in the leg veins is most likely to begin.

Summary

Investigations were carried out in 51 cases on a proposed method for the prediction of post-operative thrombosis. It was

decided that the results were not accurate enough to warrant the use of heparin and dicoumarol in those cases in which the tests were positive.

It was found that there is commonly a fall in coagulation time during or immediately after operation, and it is suggested that thrombosis, if it does occur, probably starts during this period.

I am indebted to Professor Digby Chamberlain, who proposed and guided these investigations, and on whose cases they were carried out.

INCIDENCE OF SIGNS USUALLY CONNECTED WITH THYROTOXICOSIS

WITH SPECIAL REFERENCE TO LID LAG*

BY

W. P. U. JACKSON, M.D., M.R.C.P., D.C.H.
Late Assistant Physician, Selly Oak Hospital, Birmingham

During recent observations on the coincidence of hyperthyroidism and peptic ulcer (Jackson and Pinkerton, 1949) it was noticed that a large proportion of patients with the latter complaint showed von Graefe's sign (lid lag), one of the characteristic ocular phenomena of thyrotoxicosis. This sign was first described in 1864 by von Graefe, who said: "... namentlich folgt bei Senkung der Cornea das obere Augenlid nicht." He remarked that it was not the result of exophthalmos, as it was present in early cases of thyroid disease which showed no proptosis. He considered it to be a sign pathognomonic of hyperthyroidism in the early stage: "... geringen Grade der Krankheit einen pathognomonischen Werth hat." It is now recognized that the sign is not peculiar to thyrotoxicosis (Eason, 1927) and that it may occur in normal people (Joll, 1932). Joll remarks that it also occurs in all forms of goitre, in myotonia congenita, and in all cases of proptosis.

Present Investigation

In order to determine the approximate incidence of lid lag in people without thyroid disease, and to see whether it was particularly common in cases of peptic ulcer, 600 people of all ages and approximately equal sex numbers who attended a general hospital were examined. All patients with dysthyroidism, severe illness, and prolonged pyrexia were excluded. Otherwise there was no selection, except that 38 extra cases of peptic ulcer were specially included. Other manifestations which occur in thyrotoxicosis were also looked for in this series. Preference for hot or cold weather was noted, and the subjects were questioned about excessive sweating. Lid lag, lid retraction, exophthalmos, enlargement of the thyroid gland, and tremor of the outstretched fingers were looked for. The heights and weights of all those over 18 were noted where practicable.

For present purposes lid lag is defined as occurring when a white band of sclera appears between the upper lid and the cornea on following a moving object downwards with the eyes. If lid retraction is present lid lag can be considered to exist only if there is a definite widening of the band of sclera already visible. This is the most objective way of defining lid lag, although in those whose lid is usually held at a low level there may be a degree of lagging of the upper lid without any sclera coming into view. The results are shown in Table I.

TABLE I.—*Results of Investigation*

	Total No.	No with Lid Lag
Whole series	600	85† (14%—or 10% of whole series excluding ulcer cases)
Patients with peptic ulcer ..	76	23 (33%)
,, ,, lid retraction .	14	8 (57%)
,, ,, exophthalmos	3	3 (100%)
,, ,, non-toxic goitre	35	5 (14%)
,, ,, fine tremor ..	11	

† 58 males, 27 females.

Types of Eyelid Movement.—All cases of lagging of the upper eyelid were not alike. The band of sclera might appear during the whole movement of the eyeball or during any part of it. In other words, the lag might begin as soon as the eyeball started to descend, or the lid might move normally at first and lag later. The movement might be smooth or jerky. The lag in some cases was variable, at times being pronounced and at other times not being elicited at all. In five cases it was unilateral, and in two there was actually a reverse or upward movement of the eyelids as the eyeballs started downward. In one person the lid retraction was unilateral.

Lid Lag in Relation to Other Observations

The male sex predominated in the ratio of 2 to 1. All age groups produced subjects with lid lag, but it was more common in those over 40 (see Table II).

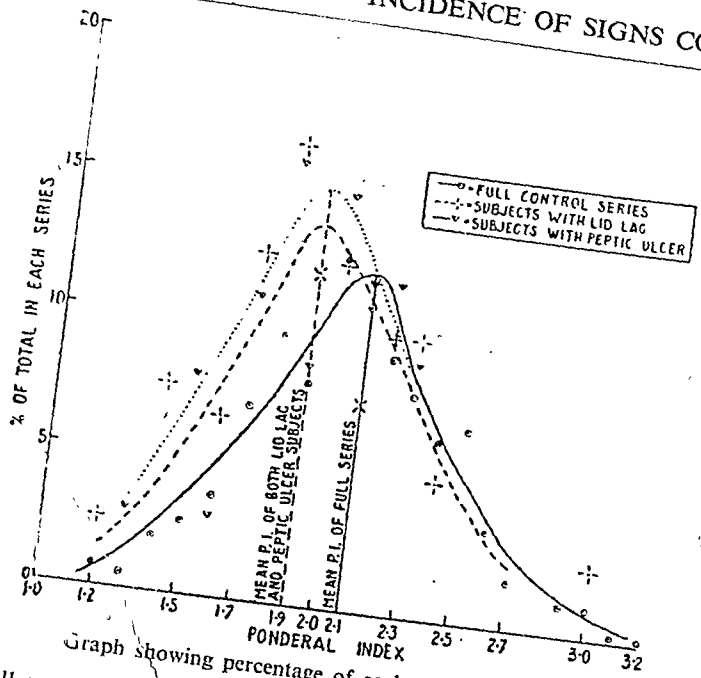

TABLE II.—*Age Incidence of Lid Lag*

Age	Total No. of Subjects	No with Lid Lag
0–9 years	31	3 (9.7%)
10–19 ,, .. .	50	2 (4%)
20–29 ,, .. .	50	2 (4%)
30–39 ,, . ..	72	8 (11%)
40–49 ,, .. .	115	20 (17.4%)
50–59 ,, .	132	22 (16.6%)
60–69 ,, . .	107	21 (19.6%)
70–79 ,, ...	43	7 (16%)

Eight of the 14 subjects with lid retraction also showed lid lag, as did all three with exophthalmos and five out of the 35 with simple goitres. Of the 76 cases of peptic ulcer 23 (33%) showed lid lag. This incidence is significantly higher than that of lid lag in the control series (10%). The impression was formed that lid lag was more common in thin people, and since peptic ulcer characteristically occurs in people with a low ponderal index (P.I.) (Draper, 1930; Robinson, 1938) this was suspected of being the explanation of the frequent occurrence of lid lag in peptic ulcer subjects. To test this hypothesis the P.I.‡ of all those over 18 was worked out, and all fell between 1.2 and 3.2. The number of subjects pertaining to each index was noted and expressed as a percentage of the whole. Thus three subjects (0.5% of the total) had a P.I. of 1.3. These percentages for each P.I. referring to (1) all the subjects, (2) the peptic ulcer subjects, and (3) those showing lid lag were plotted separately (see Chart). The mean P.I. in the full control series was 2.1 (slightly in excess of the mode), while in subjects with peptic ulcer and in those showing lid lag it was 1.9. The chart thus confirms the tendency for lid lag to occur in people of slim build, but it seems unlikely that this factor alone can explain its excessive appearance in peptic ulcer subjects. However, the male preponderance in both peptic ulcer—about 4 : 1 (Stewart, 1923; Ryle, 1932; Tidy, 1944;

*Based on a paper read at the South African Medical Congress, Capetown, September, 1949.

‡The ponderal index in this investigation was calculated by dividing the weight in pounds by the height in inches.

Graph showing percentage of each ponderal index.

Sallström, 1945)—and lid lag—2 : 1 in this series—may also offer a partial explanation.

Other Findings.—The occurrence of 28 cases of greatly enlarged non-toxic thyroid glands in subjects resident in Birmingham puts the approximate rate of simple goitre in this city at 5.6%. It was noted that 125 people preferred cold weather, 273 hot weather, and the remainder were indifferent. All subjects under 20 preferred the heat. Therefore only in young people can preference for cold weather be considered an important diagnostic feature in borderline hyperthyroidism unless there has been a recent change in preference.

Assertions of excessive sweating were not uncommon, but revealed nothing of particular interest. The very fine rapid tremor generally considered characteristic of hyperthyroidism was found 11 times.

Mechanism of Lid Lag

Von Graefe (1864) believed that the cause of his sign was a disturbance of lid musculature, probably affecting Müller's muscle through the sympathetic system. He observed that morphine abolished the sign. Pochin (1939) believed that the lid retraction (usually combined with lid lag) in Graves's disease was associated with spasm of the levator palpebrae superioris and not with affection of the involuntary muscle. Joll (1932) considered that lid lag was often a "mechanical consequence of forward displacement," but this cannot explain its occurrence in normal people. The observations reported above do little to elucidate the mechanism of the lagging, but suggest that it is more common in thin people.

Summary

The examination of 600 subjects demonstrated the frequency of lid lag, apart from its hyperthyroid connexions. The incidence of certain other signs characteristically occurring in thyrotoxicosis was also estimated in this series. It seems that lid lag is particularly common in people suffering from peptic ulcer, and so cannot be of help in the diagnosis of mild degrees of hyperthyroidism in patients with ulcer.

STATISTICAL NOTE

(1) The male sex preponderance is very highly significant, the difference between proportions being ten times the standard error.
(2) The high incidence of lid lag in peptic ulcer subjects is also significant. The differences between percentages is three times the standard error.
(3) The difference between the mean P.I. of ulcer cases and of the control series and between lid lag cases and controls is over three times the standard error in each instance. The apparent high frequency of lid lag in thin people and in ulcer subjects is thus highly significant.

I should like to thank Mr. Kelman, the medical superintendent, for permission to investigate patients at Selly Oak Hospital.

ACTINOMYCOTIC EMPYEMA

BY

HAROLD W. BOWYER, M.D.

Assistant Visiting Physician, Bolton Royal Infirmary

Massive empyema due to actinomycosis is uncommon enough to warrant description of a case. Price (1941) states that the empyema is rarely large and the primary lesion seldom pleural. Until recently the prognosis was regarded as unfavourable, death resulting from exhaustion and toxaemia. Penicillin therapy, however, has given promising results in cases cited by Hamilton and Kirkpatrick (1945) and others in this country, and by American authors.

The following case is of interest because a total dosage of over 25,000,000 units of penicillin extending over a period of 56 days was necessary to overcome the infection. Repeated aspirations were necessary owing to the encysted nature of the empyema.

Case History

A carter aged 49 was seen by me in consultation with his own doctor on February 12, 1949. He gave a history of sudden onset of right-sided chest pain and rigors on December 22, 1948. After a few days in bed he resumed his normal activities but did not feel well. On January 29, 1949, the pain returned accompanied by cough and feverishness. His doctor suspected a pleural effusion, but was unable to obtain fluid from the pleural cavity. The temperature was remittent and the dullness increased in spite of treatment with sulphamezathine. The patient had frequent profuse sweats, looked toxic, and had lost weight.

I found him to be moderately dyspnoeic. His pulse rate was 84, regular, and of good volume; respirations, 28; temperature, 101.3° F. (38.5° C.). The apex beat was in the fifth interspace outside the nipple line. His blood pressure was 140/75 mm. Some clubbing of the fingers was present. Examination of the chest showed well-marked signs of a pleural effusion, with stony dullness extending from the base of the right lung to the third interspace posteriorly and forward to the anterior axillary line. B.S., V.F., and V.R. were greatly diminished. There was no bulging of the intercostal spaces. An area of paravertebral dullness was found on the opposite lung. The urine showed no abnormality.

On February 13 he was admitted to the Bolton Royal Infirmary. A radiograph revealed a massive pleural effusion of the right side of the chest, and 10 ml. of thin greenish foul-smelling pus was aspirated and sent to the pathology department. The patient was then put on penicillin, 250,000 units daily in three-hourly injections. On February 24, on receipt

of the pathological report, the dosage was increased to 500,000 units daily.

Pathological Report.—Greenish foul-smelling pus containing a moderate number of small yellow granules. Stained film: numerous pus cells, numerous fusiform bacilli, small Gram-negative coli and bacilli, a moderate number of clumps of filamentous organisms of fungal morphology. This specimen was referred to the Fungus Reference Laboratory, which reported that *Actinomyces israeli* was present.

On February 22, 2 pints (1.14 litres) of pus was aspirated and 100,000 units of penicillin injected. On February 24, 1 pint 570 ml.) was aspirated. A radiograph on February 28 still showed an encysted collection in the right mid-zone posteriorly. This was much thicker and more difficult to aspirate. Rib-resection was considered, but as the fluid was centred under the inferior angle of the scapula it was decided to continue to aspirate.

By March 12 the temperature finally settled. On the 14th a radiograph still showed some encysted fluid. Aspiration failed. On March 18, 6 oz. (170 ml.) of pus was aspirated after screening, and penicillin was injected. On April 8, 6 oz. of pus was aspirated and 100,000 units of penicillin injected.

Pathological Report of Pus.—On March 9:—Direct smear: numerous pus cells, very scanty Gram-negative bacilli, no actinomyces seen. Cultures: no growth on blood agar. On March 18:—Direct smear: numerous pus cells, no organisms. Culture (aerobic and anaerobic): no growth.

An *x*-ray report on April 12 stated that the fluid seemed to have cleared from the right side and had left some residual pleural thickening.

Other Investigations.—A blood count on February 14 showed: Hb, 68%; red cells, 4,435,000; colour index, 0.77; white cells, 14,000 (eosinophils 81.5%, basophils 0.5%, lymphocytes 11.5%, monocytes 6.5%). Sputum examination on February 17: *M. tuberculosis* not found; moderate number of pus cells, fairly numerous epithelial cells, a few "dust" cells; no malignant cells seen. Blood sedimentation rate on February 21: first hour, 118 mm.; second hour, 125 mm. (Westergren). Sputum on February 25: moderate number of pus cells, fairly numerous squamous cells, fairly numerous dust cells, no malignant cells; *M. tuberculosis* not found. Culture:—Mixed: haemolytic streptococci and *Neisseria catarrhalis*.

In addition to intramuscular penicillin (total dosage 25,000,000 units) and intrapleural penicillin (400,000 units) the patient received potassium iodide, 30 gr. (2 g.) thrice daily.

He was discharged home on April 18, having been ambulant for ten days. He had gained weight and looked and felt very well.

I am greatly indebted to Dr. G. Manning, pathologist; Dr. Brash, radiologist; and Dr. Dawson, resident medical officer, for their assistance in the investigation and treatment of this case.

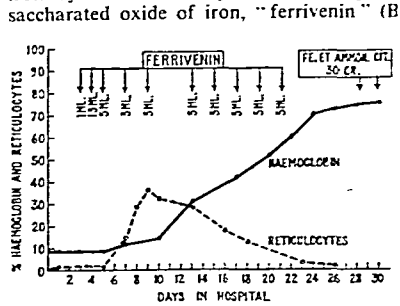
Price, F. W. (1941). *Textbook of Practice of Medicine*, 6th ed., p. 1,269. Oxford Medical Publications.

The American Heart Association is publishing a quarterly journal entitled *The American Heart*, the object being to obtain broader public understanding and support of the association's programme in the field of cardiovascular disease. Approximately $700,000 has been allocated for heart research this year by the association and affiliated organizations. According to a report in the *New York Times* (September 13, 1949) the United States Public Health Service is also launching a nation-wide attack on heart disease. A programme involving expenditure amounting to over $8,000,000 has been planned by the National Heart Institute. Among the subjects which are to be specially studied are: environmental and hereditary factors; dietary factors; new surgical methods; the usefulness of new drugs and new substances such as ACTH and cortisone; new diagnostic instruments such as the electrokymograph and the ballisto-cardiograph.

Medical Memoranda

Unusual Case of Nutritional Anaemia

The following case of nutritional anaemia is worthy of record because of the history.



CASE REPORT

A boy aged 9 was admitted to hospital on May 25, 1948, with a history of recurrent vomiting for six weeks. His previous medical history showed that he had been a full-time baby, born spontaneously after a normal pregnancy. He was the sixth of a family of seven, and all his siblings were healthy. From birth there had been a spastic paralysis of all his limbs; he had never been able to sit up and was completely helpless. Since birth his diet had consisted of milk. He refused to eat any other foods and would take his milk only from a feeding-bottle. His average daily consumption was about 5 pints (2.84 litres).

He had always tended to be constipated, but otherwise remained well until ten weeks before admission to hospital, when he had become unusually constipated and had had no bowel action for 25 days, at the end of which time he passed a very large constipated stool. Since then he had been less keen on sucking; he had often vomited after feeds, and his condition had steadily deteriorated.

On examination he was seen to be grossly mentally deficient, and was unable to speak. The skull was flattened posteriorly and there was a scoliosis of the dorsal spine. His temperature varied from 100 to 101° F. (37.8 to 38.3° C.); he was extremely pale and his face was puffy. His teeth were larger than normal, well spaced, and not carious. There was a spastic paralysis of all limbs, with permanent flexion of the elbow- and knee-joints due to contractures. Cardiac enlargement was not pronounced, but a loud blowing systolic murmur was heard all over the praecordium. A blood count showed: Hb, 8.5%; red cells, 1,020,000; C.I., 0.42; white cells, 11,400 (polymorphs 54%, basophils 1%, lymphocytes 38%, monocytes 7%). The red cells were severely microcytic and hypochromic. These figures were confirmed by the Department of Medicine, Aberdeen University. Plasma proteins were 7.7 g. %, with an albumin/globulin ratio of 1.24 to 1. A radiograph showed abnormally slender bones with delayed ossification and severe general decalcification.

The patient refused to take iron by mouth, and in view of this and the extreme degree of anaemia it was decided to give iron by intravenous injection. The preparation used was a saccharated oxide of iron, "ferrivenin" (Bengers), which contained 20 mg. of iron per ml. Small doses of 1 ml. and then 1.5 ml. were given on consecutive days at the beginning of treatment, and thereafter 5 ml. on alternate days to a total of 42.5 ml. On the day after the third injection the temperature rose to 104° F. (40° C.), but, despite this, the patient looked much better. One injection was omitted, and his temperature settled. He remained afebrile during the remainder of the treatment.

The haemoglobin and reticulocyte response to therapy are shown on the accompanying Chart. Within three weeks the haemoglobin was 70%, and he had been persuaded to increase the range of fluid feeds, but he still refused all solids. Iron and ammonium citrate in 10-gr. (0.65-g.) doses was thereafter given three times daily in bottle feeds.

COMMENT

The only demonstrable dietary deficiencies in a boy of 9 fed since birth solely on milk were a severe iron-deficiency anaemia and poor calcification of bones. Milk as a food is an incomplete source of nourishment, but in such large quantities as this patient consumed there is an adequate supply of all the essential food elements except iron. The vitamin D supply is variable, but is probably insufficient in the absence of sunlight. The response to intravenous iron was rapid, and the injections were well tolerated.

M. MCLEAN, M.B., Ch.B., D.C.H.,
Medical Registrar,
Royal Aberdeen Hospital for Sick Children.

An Extrarenal Hypernephroma

The following case was shown at a pathological meeting of the Section of Surgery of the Royal Society of Medicine on January 7, 1948.

CASE REPORT

The patient, a man aged 58, was first seen at Edgware General Hospital in October, 1944. He had had sacro-iliac backache for two years, but nothing significant was found on examination. He also complained of dysuria and nocturnal frequency in December, 1945, when the backache and urinary symptoms had increased, and of lassitude and loss of weight.

On examination his general appearance was cachectic. A large solid tumour was found emerging below the left costal margin and filling the upper left quadrant of the abdomen and the epigastrium. It moved on respiration, was dull to percussion, and was not tender. The liver was not enlarged and there was no ascites. The blood pressure was 120/70. A blood count showed: red cells, 4,000,000; haemoglobin, 78%; white cells, 10,800. The urine was normal. Radiographs of the spine revealed osteoarthritis but no metastatic deposits. Barium studies showed the stomach displaced to the right and hypertrophy of rugae at the greater curvature; the splenic flexure was displaced downwards. An intravenous pyelogram showed the left kidney rotated and displaced downwards to the level of L4. Anatomy and function were normal.

Operation (January, 1947).—A left paramedian incision was made. A normal spleen presented in the epigastrium on the surface of a large retroperitoneal tumour. The spleen and tumour were excised after freeing the latter from the upper pole of the kidney. A tough layer of connective tissue containing the suprarenal gland intervened. Recovery was uneventful.

The specimen is a solid ovoid tumour weighing 7½ lb. (3.4 kg.) (Fig 1). Microscopically, the appearances are characteristic of a hypernephroma. The cells are polygonal, with a foamy cytoplasm. The connective-tissue septa are thinner and less abundant than usual (Fig. 2).

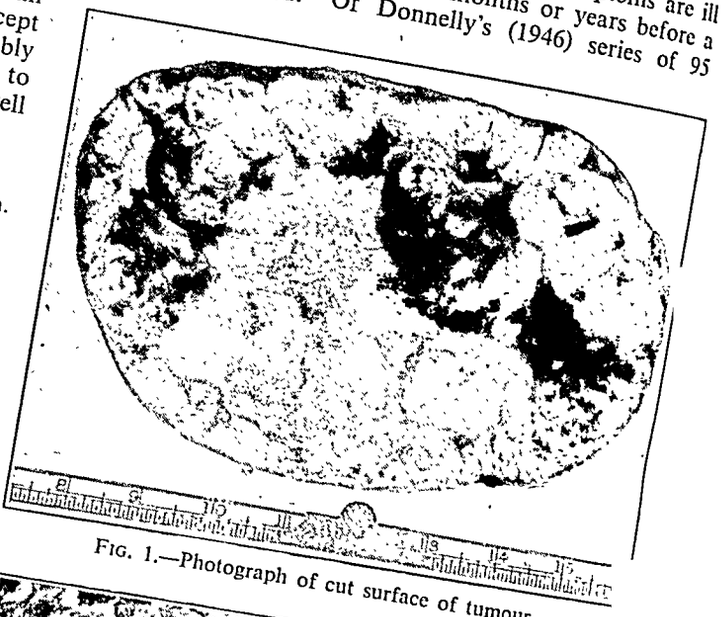


FIG. 1.—Photograph of cut surface of tumour.

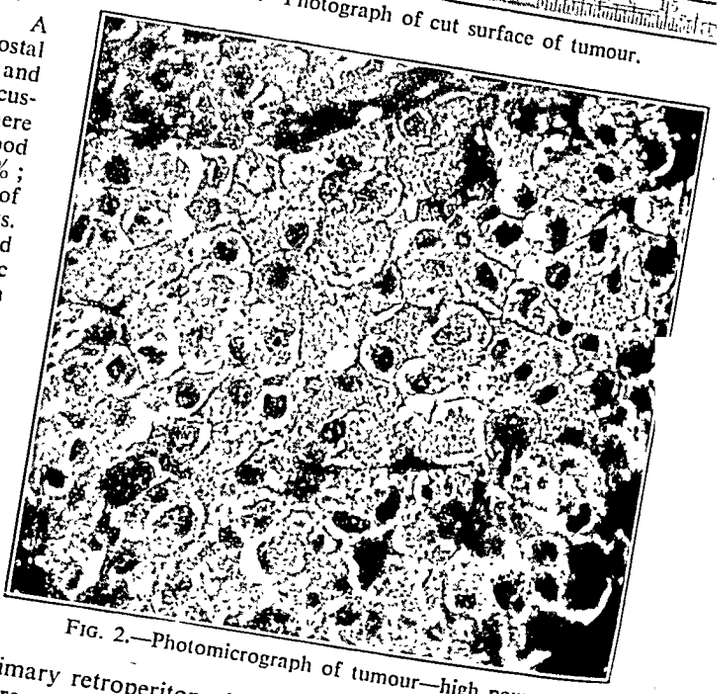

FIG. 2.—Photomicrograph of tumour—high power.

COMMENT

Tumours with the histological appearance of adrenal carcinomata—the so-called hypernephromata—occur much less commonly as independent retroperitoneal growths than within the substance of the kidney.

Surveys of large numbers of primary retroperitoneal tumours (Goebell, 1901; Donnelly, 1946) indicate that adrenal-cell tumours account for only 3 or 4%; the remainder consist of a wide range of tumours corresponding to all the varieties which may occur in the adult urogenital organs. They are thought to arise from remnants of the embryonal urogenital apparatus (Hansmann and Budd, 1931). Death results from dissemination by lymphatics and veins as well as from direct extension to vital organs. Bone metastases are relatively infrequent (Ewing, 1940).

Complete extirpation of the tumour while still self-contained obviously offers the best prospects of cure. The operability rate is generally low because symptoms are ill-defined and may remain so for months or years before a mass is discovered. Of Donnelly's (1946) series of 95 primary retroperitoneal tumours, 82 were explored and 34 were considered operable. The operative mortality was 19.7%.

The most valuable diagnostic aids to earlier diagnosis are barium *x*-ray films and pyelography, which reveal displacements of the viscera and exclude growths of the gastro-intestinal and urinary tracts. Loss of weight and strength are the most constant symptoms. Exploratory laparotomy, however, often offers the only means of discovering the exact nature of the tumour.

I am indebted to Miss M. H. Shaw for the photographs.

Reviews

NEUROHISTOLOGY

Atlas of Peripheral Nerve Injuries. By William R. Lyons, Ph.D., and Barnes Woodhall, M.D. (Pp. 339. £4.) Philadelphia and London: W. B. Saunders Company. 1949.

This superbly produced monograph is concerned chiefly with the histological appearances of damaged nerves removed at operation. It is not a complete atlas of peripheral nerve injuries as there are few clinical photographs, and none illustrating motor or sensory disturbances. But provided that these limitations are recognized the reader will not be disappointed.

The American organizations for treating war injuries of the peripheral nerves were a good deal less compact than our own. There was no one comparable with George Riddoch to guide policy, and in consequence some of the work was done by men of relatively limited experience and without any predetermined plan. Although this diversity had obvious drawbacks there were some compensations, one of which was the immense variety in the material sent for histological examination. Variations in time between injury and operation were most significant, some nerves being repaired earlier, and others much later, than was the practice in the British nerve injury centres. Some surgeons amused themselves by wrapping the suture line with various materials and later gave the pathologist the chance of observing the effect of these wrappings on the underlying nerve. The result is an atlas of the morbid anatomy of nerve injuries in man which is as complete as surgical considerations will permit. Indeed, the profusion of beautiful photomicrographs is such that the reader begins to feel the aching behind the eyes and the painful swelling of the ankles that afflict the earnest picture-gazer who has spent a whole day at the Louvre. Some of the photographs are frankly repetitious, and their omission would have been beneficial.

Modern neurohistology is so enchanting that the morbid anatomist will enjoy this collection simply as an exhibition of the astonishing diversity of morphological changes that result from nerve injury and regeneration. This work is not only a great credit to its authors: it is a tribute to all who have contributed to the perfection of staining methods for nervous tissue and to modern photomicrography. The surgeon's interest will be different. He will realize the extent to which his practice must be guided by the findings of the morbid anatomist. The tissue disturbance caused by a fast-moving particle is far more widespread than usually supposed, and in no tissue are its effects more clearly revealed than in the peripheral nerve. In consequence, the stumps of a nerve severed in a war wound must be resected more generously than those of a nerve damaged in an industrial or domestic accident. He will find that the theoretically ideal primary suture is unsatisfactory in practice. He will learn something about the curious pathology of traction injuries which (it is hoped) will convince him that operative intervention is not likely to be of much use. He will learn, too, about the fate of autogenous and homogenous grafts.

This is not a book for bedtime reading; it is not one that should be in every surgeon's and morbid anatomist's library; but it is a work that should be in the possession of everyone who has any interest at all in the peripheral nervous system. The authors hope that, "if the professional, administrative, and financial hazards of surveying large groups of rehabilitated war veterans can be surmounted through governmental or private channels, the influence upon peripheral nerve regeneration of the neuropathological changes that have been described in this atlas will be the subject of a separate monograph within the next few years." Perhaps it may encourage them to know in advance how much further we shall be in their debt if they succeed, as we trust they will, in this second and more formidable undertaking.

H. J. SEDDON.

PULMONARY NEOPLASMS

Bronchiogenic Carcinoma and Adenoma. By B. M. Fried, M.D. (Pp. 306; 118 illustrations. £1 13s.) London: Baillière, Tindall and Cox. 1948.

This book, which discusses a subject that has achieved in recent years a practical importance that it will maintain, is a useful study but not an authoritative account. The illustrative radiographs are below the standard one expects to-day, and not one lateral picture is used. Some of the radiographs are produced as negatives and some as positives—uniformity is preferable. The photographs of specimens are very poor.

It is disturbing to see the term "superior pulmonary sulcus tumour" perpetuated, for the name means little or nothing and should be abandoned. In the description of metastases it is stated that the liver is involved in about 40% of cases, and the contralateral lung in about 30%. Although not specifically stated, one presumes that these are necropsy figures, for they are certainly not true of present clinical practice in England. The policy of using observations made in the necropsy room projected backwards to embellish a clinical picture is liable to be most unsatisfactory and, although having its uses, is somewhat out of date. Far too much teaching in the past has been of advanced disease, which renders it more difficult for the student and practitioner to recognize the earlier phases when they meet them before the stage of impending death.

A great deal of the space devoted to case histories might have been better used in a fuller discussion of such a dangerous topic as aspiration biopsy, or a more detailed consideration of the significance of pleural fluid, or of bronchoscopy, or of a number of other fundamental matters. The remarks on radiotherapy and surgery are purely "scissors and paste" products and carry no direct authority. Bronchial carcinoma is to-day a surgical disease, and the surgery section should either be written by a surgeon or omitted. The chapters on bronchial adenoma are indifferent, and it is difficult to see why the one on mediastinal tumours was included at all.

The book contains a full bibliography and is of value as a work of reference for this, and for the reviews of the incidence and aetiology of the condition.

R. C. BROCK.

OPERATIVE SURGERY

Operative Technic in General Surgery. Edited by Warren H. Cole, M.D., F.A.C.S. With introduction by Frank H. Lahey, M.D., F.A.C.S. (Pp. 951; 521 figures. No price.) New York: Appleton-Century-Crofts, Inc.

The latter part of the nineteenth century might be described as the Elizabethan period of operative surgery, when enterprise was so widespread and the field so fruitful that achievement was great. This rich era of technical advance was consequent upon the discovery of the causes of infection and their mastery. Since then some surgeons have thought the harvest had been fully reaped, and from time to time even great leaders like Erichsen and Moynihan made the mistake of expressing such an opinion. Great

advances have nevertheless been made in recent years, and no doubt there are others to come.

An account of some of the recent advances will be found in this book, which is edited by Professor Warren H. Cole, of Chicago, who was recently in this country and visited all the university clinics. The work is compiled by 34 well-known American surgeons. There are sections on abdominal incisions, by Frederick A. Coller and K. F. Maclean: on the surgery of the stomach and duodenum, by Waltman Walters and L. R. Dragstedt; on the thyroid, by J. de J. Pemberton and B. M. Black; on vascular lesions, by Daniel Elkin and M. E. DeBakey; on the hand by H. S. Allen and Sumner L. Koch; and on the pancreas and adrenal, by Alexander Brunschwig, to mention only a few of the distinguished contributors.

References (almost exclusively from American sources) follow certain sections, but in others they are scanty or absent. The printing is clear and the text easily readable; illustrations are plentiful, and the line drawings are good, though less is to be said for the few coloured plates. As a textbook of operative surgery it is open to the criticism of unevenness, since some of its aspects are discussed thoroughly and others scantily or not at all. Overlooking this, however, there will be found a series of articles by well-known masters for whom no commendation is necessary, and these alone will make the book attractive to many surgeons. Dr. Frank Lahey writes an introduction in which he points out that the book has the great advantage of being written by men experienced in the particular subjects about which they write. This is its great merit and compensates for any incompleteness of the subject-matter.

LAMBERT ROGERS.

THE THYROID

The Thyroid and its Diseases. By J. H. Means. Second edition. From the Thyroid Clinic of Massachusetts General Hospital. (Pp. 571. £3 12s.) Philadelphia and London: J. B. Lippincott Company. 1949.

Since the first edition of this book appeared in 1937 so many advances have been made that nearly all the sections have now been rewritten. Professor Means has been in close contact with most of these advances, so that he can present full, clear, and authoritative discussions of such subjects as the metabolism of iodine, the pharmacology and physiology of the thyroid and thyrotropic hormones, the pharmacology of the antithyroid drugs, the new light thrown on thyroid physiology by the use of radioactive iodine as tracer, and the use of this substance in therapy. All these and many more advances are lucidly explained and fairly discussed. Full and up-to-date accounts of the diseases of the thyroid are an important feature of the book. A valuable chapter is contributed by Oliver Cope on the surgery of the gland, with particular reference to the special knowledge required by the thyroid surgeon and the factors influencing his plan of operation. Professor Means's view on the place of antithyroid drugs is summarized by his conclusion that "drug therapy is certainly preferable to mediocre surgery," a statement which would be accepted in this country.

The diagnosis of hyper- or hypothyroidism is not always easy on clinical grounds alone. The author assesses the value and the shortcomings of the basal metabolic rate as a diagnostic aid, and discusses other tests of thyroid function. He points out, however, that laboratory tests do not in any way replace the clinical examination. The cold hand, dry or moist, almost excludes hyperfunction of the thyroid: an increasing need for bed covering is suggestive of myxoedema. The characteristic entrance of a thyrotoxic patient into the consulting-room is vividly described, equally the good nature of the myxoedematous person who often becomes still more pleasant when "thawed out by thyroid."

There is in this book much valuable information and instruction for all interested in the thyroid, and full lists of references at the end of each chapter provide the link with the original literature.

C. L. COPE.

COMMON-SENSE PSYCHIATRY

The Commonsense Psychiatry of Dr. Adolf Meyer. Edited by Alfred Lief. (Pp. 677. $6.50 or £1 19s.) New York and London: McGraw-Hill Book Company, Inc.

Most of the papers in this volume date from 30 or 40 years ago, and it is remarkable how fresh and topical they are to-day. This book contains not only a representative collection of Meyer's papers but a biography of their author and a history of psychiatry during the last 50 years. It shows how the author has led psychiatry away from an exclusive interest in cerebral lesions and toxins towards the actions, reactions, and attitudes of the individual towards the whole of his environment. Some such reactions are physical, some psychical, and some psychosomatic.

Meyer therefore takes a holistic attitude towards his subject and persistently refuses to be bound by dogmata of any sort. He accepts the modern dynamic psychology, and he studies the past as well as the present and does not insist on the universal influences of complexes, especially those founded on infantile sexuality. The mentally sick person is not the sum of elements of disease but a functioning unit in society who is doing something. Hence his insistence on the paramount importance of psychiatric social work and occupational therapy. Moreover, each patient is a problem in himself, and though classification may be useful for didactic purposes patients cannot be forced into nosological pigeon-holes. Meyer insisted that sanity depends on the endurance against strains—physical, psychological, and social—and such conditions as schizophrenia are disorganizations of both organic and functional habits. He stresses the importance of the school period in preventing such disorganization of habits by giving opportunity and encouragement to constructive and active behaviour. He has been a supporter of mental hygiene, child guidance, and all methods of preventive mental medicine.

Meyer's appointment to the directorship of the Phipps Institution at Baltimore gave him the opportunity to put all these constructive ideas into practice, his patients being principally early, recoverable cases. Towards the end of his long life he devoted thought to the more general aspects of psychiatry—those relating to such problems as freedom, marriage, education, and religion. Readers of this book will find not only a fascinating historical document but stimulating and informative material which will be most useful to them in their own work.

R. G. GORDON.

SPANISH HAEMATOLOGY

Symposium de Hematologia y Hemoterapia—1948. By J. Guasch, A. Raichs, C. Trincao, and R. Surinyach. (Pp. 522. No price.) Barcelona: Miguel Servet., 1949.

Mononucleosis Infecciosa. By J. J. Permanyer Macia and P. Vintró Marcé. Preface by Professor M. Soriano. (Pp. 96. No price.) Barcelona: Ediciones Byp. 1948.

Of the seven articles in the symposium of haematology and blood transfusion four are moderately interesting. Well documented essays based on two cases each of elliptocytosis and pregnancy occurring in the course of chronic myeloid leukaemia present a clear account of the state of our knowledge of these rarities. A single case gives opportunity for

a discussion on the curative effect of splenectomy in antimony-resistant kala-azar—a subject which, though of little interest to us, is of considerable importance in paediatric practice around the Mediterranean Sea. Of the residents in the Barcelona area only 10% appear to be Rhesus-negative, in contrast to the 35% reported in Basques by Etcheverry and by Mourant. Short essays on allergy and intramedullary transfusion and an article of 228 pages on the treatment of severe neutropenia complete the volume. There seems to be little difference between standard practice in this country and that advised by the authors. This is the second volume of this type received from the Iberian peninsula within the last few months; both show great industry but little profit.

Macia and Marcé's short monograph gives a clear account of infectious mononucleosis and of the laboratory aids to its diagnosis. The clinical section follows Tidy in recognizing three main types of the disease—glandular, anginose, and febrile—but attention is drawn also to the bizarre symptom-complexes which sometimes occur. In the section on laboratory diagnosis the various modifications of the Paul-Bunnell reaction are lucidly described and evaluated. The clarity of the presentation throws the few omissions into relief. Three types of glandular fever cell described by Downey and McKinlay should have been mentioned, and the occurrence of 1–7% of the Type I cells of these workers in infective hepatitis and other virus diseases is sometimes significant. The great increase in staff-form neutrophils over segmented types in the early stages of the disease is of considerable diagnostic value, and the recognition of epidemic outbreaks in which the Paul-Bunnell reaction is consistently negative (recorded in this country by Macfarlane) is very important. The bibliography, though it includes most of the important papers, could well be enlarged. The volume is completed by some long abstracts from the foreign press. It is an unpretentious, useful monograph for isolated workers who read Spanish.

GEORGE DISCOMBE.

Dentistry in Public Health, edited by Walter J. Pelton and Jacob M. Wisan (pp. 363; £1 7s. 6d.; Philadelphia and London: W. B. Saunders Company; 1949), is an interesting book by many contributors which illustrates the interest now taken in dentistry from the public health viewpoint in the United States. A considerable amount of research in the last few years has produced valuable results, including the discovery of the role of fluorine in the prevention of caries. It is unfortunate that publicity has been given at times to work and theories that have not been fully evaluated, but in this book evidence is sifted and conclusions are not accepted without adequate supporting facts. Thus, in spite of much that has been written on the subject, it is stated that the topical application of fluorides to the teeth as a preventive measure has not yet been substantiated. It is of interest to see the extensive programme for research into public health dentistry that is proposed. It would be as well if we gave more thought to the subject in this country.

The monograph by the late Dr. Libman and Dr. Friedberg, *Subacute Bacterial Endocarditis* (edited by Henry A. Christian and reprinted from Oxford Loose-Leaf Medicine; pp. 113; illustrated; £1 1s.; New York and London: Geoffrey Cumberlege, 1949), is a comprehensive and valuable work based upon large numbers of cases. The pathology, diagnosis, and treatment are presented in detail, but the authors have focused little attention on this infection in congenital heart disease. It is in such patients, in whom the myocardium remains unscathed, that the best results of therapy with antibiotics are to be expected. There is no reference to an important diagnostic method in non-cyanotic congenital heart disease—the use of an arterial as opposed to a venous blood culture when there is a left-to-right shunt. Any means of determining the diagnosis more quickly is of added value now that specific remedies are available. Of interest to readers in this country will be the good colour plate showing Janeway lesions, but the other illustrations are indifferent. A comprehensive bibliography completes and enhances the value of this authoritative monograph.

BOOKS RECEIVED

[Review is not precluded by notice here of books recently received]

The Healing Touch. By H. Williams (Pp. 406. 15s.) London: Jonathan Cape. 1949.

Freedom from Want. Edited by E. E DeTurk. Foreword by N. E. Dodd. (Pp. 207-84. $2.00.) Waltham, Mass.: The Chronica Botanica Co. London: Dawson. 1949.

Psycho-Analysis—a Modern Delusion. By F. Kenyon. (Pp. 141. 5s.) London: The Pioneer Press. 1949.

Population Trends and the World's Biological Resources. By G. C. L. Bertram, M.A., Ph.D. No. 5. (Pp. 38. 2s.) London: The Eugenics Society, and Cassell. 1949.

The Medical Clinics of North America. Mayo Clinic Number. Gastro-Intestinal Conditions. (Pp. 923—1,210 No price.) London and Philadelphia: W. B. Saunders. 1949.

Pedigrees of Negro Families By R. Ruggles Gates, F.R.S. (Pp. 267. $5.50.) Philadelphia and Toronto: The Blakiston Company. 1949.

Lehrbuch der Inneren Medizin. By H Assmann, G. v. Bergmann, and others. Foreword by H. Schwiegk and A. Jores Vols 1 and 2. Berlin: Springer. 1949.

Children of Today and Tomorrow. By E. Dukes and M. Hay. Preface by D. Mace, Ph.D. (Pp. 249. 12s. 6d.) London: George Allen and Unwin. 1949.

Office Management for Health Workers. By F. King and L. L. Feldman. (Pp. 164. 12s. 6d.) New York. The Commonwealth Fund. London: Geoffrey Cumberlege. 1949.

Kinderärztliche Notfallfibel ein Exkurs fur die Praxis. By B. de Rudder. (Pp. 134. M. 7.80.) Stuttgart: Georg Thieme. 1949.

Aus dem Leben Fritz Richard Schaudinns. By C. Kuhn. (Pp. 73. M. 3.80.) Stuttgart: Georg Thieme. 1949.

Transactions of the Ophthalmological Society of the United Kingdom. Vol. 67. (Pp. 530. 40s.) London: Churchill. 1948.

Medullary Nailing of Küntscher. By L. Böhler, M.D Translated by H. Tretter, M.D. (Pp. 386. 38s. 6d.) London: Baillière, Tindall and Cox. 1948.

Communicable Diseases and their Nursing Care. By E. Pearce, S.R.N. Foreword by W. Gunn, F.R.C.P. (Pp 392. 14s. 6d.) London: Faber. 1949.

The Human Body and its Functions. By C. H. Best, C.B.E., M.D., F.R.S., and N. B. Taylor, V.D., M.D., F.R.S Canad. 2nd ed. (Pp. 500. 18s.) London: Chapman and Hall. 1949.

A New Dictionary of Chemistry. Edited by S Miall, LL.D., B.Sc., and L. M. Miall, B.A., F.R.I.C. 2nd ed. (Pp. 589. 60s.) London: Longmans, Green. 1949.

Modern Practice in Ophthalmology, 1949. Edited by H. B. Stallard, M.B.E., F.R.C.S. (Pp. 525. 65s., plus 1s. 6d. postage.) London: Butterworth. 1949.

Lippincott's Quick Reference Book for Medicine and Surgery. By G. E. Rehberger, A.B., M.D. 14th ed. (Pp. 1,723. £6.) Philadelphia, London, and Montreal: Lippincott. 1949.

A Study of Certain British Seaweeds and their Utilisation in the Preparation of Agar. By S. M. Marshall, L. Newton, and others. Edited by L. Newton. (Pp. 184. 27s. 6d.) London: H.M.S.O. 1949.

The New York Academy of Medicine. Its First Hundred Years. By P. Van Ingen. (Pp. 573. 55s.) New York: Columbia University Press. London: Geoffrey Cumberlege. 1949.

Principles of Human Physiology (Starling). By C. Lovatt Evans, F.R.C.P., F.R.S. Chapters on Special Senses by H. Hartridge, M.D., F.R.S. 10th ed. (Pp. 1,193. 42s.) London: Churchill. 1949.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY OCTOBER 15 1949

WORLD MEDICAL ASSOCIATION

Medical men and women from 27 countries met this week at B.M.A. House to take part in the deliberations of the General Assembly of the World Medical Association. The groundwork of the meeting had been prepared the week before by the ten members of the WMA Council under the chairmanship of Dr. T. C. Routley, Secretary of the Canadian Medical Association. Dr. Charles Hill, Secretary of the B.M.A., is the new President of the WMA for 1949–50 in succession to Professor Eugene Marquis. The machine of the WMA is kept moving on its appointed course by the Secretary-General, Dr. Louis H. Bauer, of New York, who is also Chairman of the Board of Trustees of the American Medical Association. He is helped by Assistant Secretaries for Asia, Australasia, Europe, and Latin America in the persons of Dr. S. C. Sen, Dr. J. G. Hunter, Dr. Paul Cibrie, and Dr. J. A. Bustamante. The financial affairs of WMA are kept in order by the treasurer, Dr. O. Leuch, of Zurich.

The WMA has progressed far and fast since the first meeting of the General Assembly in Paris in 1947. It is now a well-organized and hard-working affair; its objects, constitution, and rules are laid down in black and white; and through the work of its committees and Council it is now well on the way to achieving the objects it has set itself. It has established relations with the World Health Organization and with Unesco, and no doubt in time it will define in co-operation with these governmental organizations those fields of activity which lie within the province of the WMA. Three issues of the WMA *Bulletin* have now appeared under the editorship of Dr. Morris Fishbein, who is also editor of the *Journal of the American Medical Association*. The *Bulletin* places on permanent record in English, French, and Spanish the results of the WMA's work, and contains matter that should be of great interest to all practising doctors who now all over the world are witnessing increasing governmental control of their professional lives. The WMA, it is important to note, is a voluntary association of the various national organizations, such as the A.M.A. and the B.M.A., which represent and protect the interests of medical men and women in various countries of the world. WHO and Unesco, being specialized agencies of the United Nations, are officered by men and women chosen by the governments represented in the United Nations. Between these official governmental agencies and the unofficial voluntary WMA there should be ample room for co-operation.

This week the Assembly once more had before it the text of the International Code of Ethics—what might be called a revised version of the Hippocratic Oath. The need for this was felt because of the crimes committed by German medical men during the recent war, a report on which was one of the early activities of the WMA. It is of course not easy to draft a code that will conform with the ethical standards of various countries, these being so intimately linked with the various world religions. So it has been proposed that each nation must be able to vary the code, so long as its main principles are not infringed. Ten national associations have already adopted it as it stands.

Last week the Council gave much time to a study of a long report on postgraduate education, and finally agreed that "after the training ordinarily prescribed in a medical school course there should be an additional period of training in an approved post before engaging in independent practice." It was felt strongly that an effort should be made to increase the facilities for postgraduate study in countries foreign to the postgraduate, although it was realized that certain legal difficulties might be an obstacle, which the national medical associations are being asked to try to overcome. Another important proposal which came before the Assembly was for an investigation into the social security schemes existing in different countries and their effect upon the quality and efficiency of medical services and also upon the relationship between doctor and patient. Such a study would seem to be of the highest value in these days of rapid change. In relation to this an inquiry is to be made into the medical man-power in different countries, a subject in which there seems to be much interest. Among some of the other matters considered was the question of distributing medical journals and textbooks, in connexion with which Unesco has done useful work in promoting international co-operation between national libraries. Unesco, it may be recalled, is trying to co-ordinate the meetings of international medical congresses so that there will be no overlapping in the timetable of these, but from the words used in a Unesco document on this subject the WMA is asking Unesco whether it is to be understood that it is seeking to determine the agenda of these congresses. This would seem highly unlikely, but clarification is clearly needed.

The general work of this week's Assembly will be summarized in next week's *Journal* so that the reader may have an idea of how WMA is setting about achieving the first of its objects, which is "to promote

closer ties among the national medical organizations and among the doctors of the world by personal contact and all other means available." The second object is "to maintain the honour and protect the interests of the medical profession"; and the last, more difficult or even impossible to realize, is "to promote world peace." At least one step towards world peace is the voluntary meeting together of medical men and women from different parts of the world to discuss all those ways and means of furthering the aim of every doctor—the care of the sick, the prevention of disease, and the maintenance of health. In this work it is to be deplored that the medical profession of the U.S.S.R. and its satellite countries does not see fit to take part—eloquent testimony to the perils of the political control of medicine.

MR. BEVAN'S REVIEW OF N.H.S.

A large crowd of journalists gathered in the Ministry of Health last week to hear Mr. Aneurin Bevan give a review of the first year of the National Health Service. This he did in a skilful and disarming manner, and as advocate in his own cause obviously could not be expected to expose those deficiencies in the Service which the medical profession now sees. One year, he said, was a very short time on which to base a judgment, but he claimed that "the first year has been remarkably good," and for this paid his tribute to all those who were concerned in the transition. The Health Service must be seen as a gigantic change-over from the private pocket to the public purse, and when he was asked later how far actual expenditure had exceeded that originally estimated in the White Paper he replied, "I should think about twice." A Select Committee of the House of Commons has already investigated the expenditure in the N.H.S. and there are obviously many factors that must have made a more exact estimate difficult. But if the Minister can make one mistake of such magnitude it is not out of the question that he may make another. For example, to a question about the remuneration of general practitioners he answered: "So far there is conclusive evidence that we have more than honoured the Spens recommendation." One point that emerged clearly from the recent discussions between the B.M.A. and the Ministry of Health was that the evidence was by no means conclusive. Then again, when he was asked whether he did not think that the remuneration of general practitioners was disproportionately low when compared with the pay of dentists and opticians he refused to accept that this was the case, stressing the fact that 52% of the gross earnings of dentists must be regarded as expenses. Yet there is evidence that in Scotland the average net remuneration of the general practitioner there is much less than the average net remuneration of dentists; and when Mr. Bevan went on to observe that dentists worked all kinds of hours he presumably did not wish to leave his audience with the idea that the general practitioner was able to fit his work into a neat timetable beginning at ten in the morning and ending at six in the evening.

In answer to a question about Sir Stafford Cripps's remark in his budget speech this year that a health tax might be necessary, Mr. Bevan said, "If by tax is meant payment by the patient at the moment when the patient needs treatment, we set our faces against it." One of the principal worries in the Service was, he said, over-prescribing. The 14,000 chemists in the scheme had had to deal with 187,000,000 prescriptions, and he appealed to patients not to be importunate, especially in asking for "ordinary" things like aspirins and cotton-wool. Yet when he was asked later whether it might not be a good thing if the patient were to make a nominal payment he replied that a nominal payment would not be a deterrent, and if it were large enough to be a deterrent it might prevent people from seeking medical help when needed. This, we suggest, does not allow for the fact that if the patient were to make a small payment, whether on the occasion of the first consultation with the doctor or for a prescription, he would be encouraged to use the Service with a greater sense of responsibility. It seems likely that sooner or later Mr. Bevan or one of his successors will have to overcome the Minister's desire to be a public benefactor, and will have to introduce some scheme of payment which will be a greater deterrent than mere exhortation to the public to be careful about spending money provided almost entirely out of the taxpayer's pocket.

There seemed to be some contradiction in two statements Mr. Bevan made. He said: "We must rest upon the principle that the doctor must be free to prescribe what he considers to be necessary for the care and welfare of his patient." Later on he remarked that "he had asked a small specialist committee to draw up a list of drugs which the general practitioner can prescribe which are adequate for the purpose and outside which the general practitioner need not go except in special cases." It is not clear whether he was contemplating an alternative to the present formulary, but in any case the implication is that the special cases referred to will have to be defined. In that event the freedom to prescribe will be limited.

When someone asked Mr. Bevan why private patients should not be provided with free drugs he made the usual reply that prescription is part of the service of the general practitioner and the two cannot be separated. When he went on to say that the individual citizen in Britain does not pay a weekly contribution to the

National Health Service, and if he did not enter it was not prevented from receiving something for which he was paying, he was wrong in his facts. Something like nine-tenths of the cost of the Service is borne by the taxpayer, and if he is prevented from accepting part of the benefit of the Service then he is prevented from receiving something for which he has paid. Mr. Bevan, incidentally, asked those journalists present to correct the prevalent misconception that the whole of the weekly contribution to National Insurance was a contribution to the Health Service. There had, he said, been in fact no increase in insurance contributions in respect of the National Health Service, and complained of the confusion that had arisen. This confusion was widely spread by those national newspapers which supported Mr. Bevan during the controversy over the National Health Service, and he himself now seems to wish to create a further misconception by saying that the private patient not allowed to receive drugs free of charge "is not desisting from receiving something for which he is paying."

All the financial implications of the National Health Service must be of much concern to the medical profession. In the national interest some limit must be set to the drain on the exchequer from the mounting cost of the N.H.S. If the finances of the scheme continue to get out of hand the possibilities of properly remunerating general practitioners must diminish. Some idea of the great increase there will be in hospital expenditure may be gained from Mr. Bevan's statement that there was need for 40,000 to 50,000 more nurses. He admitted that in some parts of the country the general practitioners are overworked, and at the same time praised "the thousands of devoted professional men and women who go about their work in a proper fashion." Yet he omitted to say—and unfortunately no question elicited a reply from him on this point—that general practitioners as a whole are working with a strong sense of justifiable grievance about their terms and conditions of work. Until these grievances are removed no Minister of Health will be able to say that the National Health Service is or has been a success. Referring to abuses in the Service, Mr. Bevan said that it was "a prerequisite of human behaviour that a human being should be allowed to behave, and what we must do is to give people the opportunity of behaving, study their behaviour, and make whatever corrections are necessary afterwards." This will certainly be the considered attitude of the medical profession in relation to the Minister of Health.

The Minister's speech is reported in this week's *Supplement*, and there is space here to comment on only some of his observations, many of which displayed his interest in and awareness of some of the problems that concern medicine. He showed, for example, a sympathetic grasp of the difficult question of providing for the chronic sick and the old people who require careful nursing. The problem of the chronic sick could not be tackled by providing expensive beds in hospital needed for the acute sick. Once provision had been made for this growing section of the community it should be necessary only in the last resort to use beds in "acute" hospitals for those nearing the end of their days. Mr. Bevan, too, saw the opportunities for research when on an agreed terminology medical men would be able to supply material for statistical analysis and so open up further possibilities for research, and he gave as an instance rheumatism, pointing out how valuable it would be to know in what age groups, occupations, and parts of the country the various forms of rheumatism occurred.

In his Press conference there were at least two Mr. Bevans speaking—first, the politician skilful in evading an awkward question or giving an answer which really demanded a further question to nail him down; second, the man who has a remarkable grasp of the complexities of the National Health Service and combines with this a desire to provide the people of Britain with every facility for improving and maintaining health. When the organized medical profession negotiates with the Minister of Health it prefers to meet him in the latter role.

PREGNANEDIOL ASSAYS

Many recent advances in the practice of obstetrics and gynaecology are the result of endocrine research. The need for the clinician to keep abreast of the main advances in this field and to understand the principles underlying hormone assays and biological tests was pointed out recently in this *Journal* by de Watteville and his colleagues.[1] They drew attention to the limitations as well as to the advantages of such procedures and emphasized the need for caution in the interpretation of the results. The value of estimating the output of pregnanediol, the chief but not the only urinary metabolite of progesterone, was discussed at the recent Twelfth British Congress of Obstetrics and Gynaecology, the final conclusion being that it is probably too early to assess its usefulness. Dr. G. I. M. Swyer's

contribution to the discussion appears in this issue of the *Journal*.

As a diagnostic test for pregnancy pregnanediol assay has been tried and generally found wanting. False positive readings can occur in the presence of delayed ovulation, corpus luteum cysts, and overactivity of the adrenal cortex; and false negative readings are so frequent as to make the test much less reliable than many of the gonadotropin tests, at least one of which can be as rapidly performed. It is often because of vaginal bleeding after one or two missed periods that the practitioner asks for a pregnancy diagnosis test, and Bender[2] claims that in 36% of cases of true threatened abortion the pregnanediol test is negative when the gonadotropin test is positive. If abortion does threaten, a low pregnanediol excretion is held to give warning of an unfavourable outcome, but Bender points out that it is also an indication to administer progesterone with a reasonable prospect of averting miscarriage unless the condition is already irreversible. If, on the other hand, the pregnanediol excretion is normal in such cases the administration of progesterone may accelerate abortion. Pregnanediol determinations indicate that repeated progesterone failure is not a major cause of habitual abortion, and progesterone should be withheld unless the assay gives a low reading. The rate of foetal loss and of maternal toxaemia is abnormally high in pregnant diabetic women in whom there is evidence of maternal hormonal imbalance, including a low pregnanediol excretion,[3] and the results of treatment with oestrogen and progesterone, though not conclusive, are encouraging. Smith[4] claims that a fall in pregnanediol output precedes the development of clinical signs of toxaemia of pregnancy, but this has not been finally confirmed. Moreover, initial hopes, mentioned by Dr. Swyer, that the combination of a gonadotropin test positive in dilution with a negative pregnanediol test would be diagnostic of hydatidiform mole have also failed to be realized. Finally, the work of Lyon[5] has suggested that once the decline in the output of pregnanediol which sets in about ten days before labour has begun the threshold of labour has been reached, and the induction of labour may then be attempted with confidence. Dr. Swyer's findings in this respect are equivocal, and at present few obstetricians will place reliance on hormone assay when deciding whether conditions are suitable for induction.

In the non-pregnant woman pregnanediol determinations are more laborious and time-consuming because of the small amounts excreted. For the diagnosis of the occurrence and time of ovulation they have been superseded by basal body-temperature charts. But where it is suspected that childlessness may be due not to failure of conception but to failure of nidation because of poor progestational response in the uterus[6] there may be a place for pregnanediol assays, for if the total amount excreted is small or limited to a few days the infertility may be due to a defective luteal phase and substitutional therapy with progesterone might be helpful. Functional uterine haemorrhage is another disorder in which pregnanediol estimations might provide useful information. McKelvey and Samuels[7] have shown that when the bleeding is characterized by asynchronous shedding of the endometrium there is an abnormal persistence of pregnanediol in the urine during the bleeding phase. Anovular haemorrhage, on the other hand, as in metropathia haemorrhagica, might be recognized by the pregnanediol content of the urine being very low or *nil* over a period of weeks. Most cases are diagnosed by curettage, but in young girls there is a proper reluctance to perform an operation, and these assays may then have some value. The time for this, however, except as an experimental study, has not yet arrived, and indeed the practical value of pregnanediol tests is clearly strictly limited. Dr. Swyer goes so far as to conclude that they are of such little help to the clinician that every effort should be made to find a method of estimating the level of progesterone in the blood, despite the fact that as a rule the concentration of hormones and their products is lower in the blood than in the urine.

The theoretical basis of pregnanediol assays lies in clinical observations that the amount in the urine, broadly speaking, reflects progesterone activity in the body. But Marrian,[8] a leading authority in this field, now casts doubts on the validity of this basic assumption. Despite this, however, he acknowledges that there is a considerable weight of evidence that pregnanediol determinations may be useful clinically, and therefore he urges clinicians to continue to test the results without prejudice and biochemists to improve still further the methods of assay. The time has certainly not yet come when pregnanediol estimations can be regarded as a useful routine laboratory procedure for general application, but it is to be hoped that a few centres, well equipped for accurate and controlled studies, will continue to work on this problem.

CHANGES IN USE OF HOSPITALS

An important statement from the Ministry of Health published this week in the *Supplement* comments on the procedure to be adopted when a hospital board wants to change the use to which a hospital has been put. Powers are delegated to the board subject to the Minister's direction, and "he cannot ignore representations made to him by members of the public and of the profession." If a

board wishes to change the use of a hospital, "he may feel bound at any time to call upon a board to report to him their reasons for adopting their new policy." The circular emphasizes that boards should consider the possible loss of service to patients and disturbance of medical staff. Where a hospital of long-standing repute is concerned, the board is required to give the medical staff an opportunity of having its views considered, orally if possible, by the board or its planning committee. In some cases an open meeting may be desirable where members of the public can express their views.

The circular points out that local loyalty is of great importance, and the Minister asks boards to make sure that they do not deprive patients of hospitals where general practitioners of the neighbourhood may treat them. The Minister considers that it is "very valuable for the general practitioner service of the district when the family doctor has access to beds where patients . . . can be in his charge and he knows he can readily call upon the services of a consultant for a second opinion." The Minister emphasizes that cottage hospitals must not be regarded merely as buildings providing additional accommodation for relieving pressure on beds at the district general hospital. This circular should have a salutary effect in some regions where boards are proposing to change the use of hospitals. In particular, we may hope that the decisions on the future of the Lock and Paddington Green Hospitals will be reversed.

PARENTERAL FEEDING

In recent years much interest has been shown in the use of amino-acids and protein hydrolysates for feeding in certain categories of illness in which the patient cannot be fed adequately by mouth. The indications for parenteral feeding are inability to ingest, digest, or absorb sufficient quantities of food over such a period of time that convalescence is jeopardized and, perhaps, the chance of survival prejudiced. The most recent information on the subject of amino-acids and protein hydrolysates was discussed at the end of last month in London at a symposium held by the Food Group of the Society of Chemical Industry, and a report of some of the papers which were read appears elsewhere in this issue. The available evidence indicates that nitrogen equilibrium can be attained and the protein needed by normal adult animals, including man, can apparently be supplied, provided energy requirements are met, by injecting into a vein properly prepared hydrolysates of biologically efficient proteins or by the provision of the essential amino-acids and an additional nitrogen source such as glycine. In general, the experiments have not been continued long enough to show that all the physiological requirements of the adult organism for nitrogen can thereby be met. There is no evidence that intravenous administration is nutritionally superior to the oral route if the latter is practicable, but protein hydrolysates are disagreeable to take by mouth. It is seldom possible to give regular intravenous injections of more than the equivalent of 75 g. of protein and 300 to 400 g. of glucose daily. If hydrolysates are injected too quickly nausea and sometimes vomiting may lead to less efficient use of the constituent amino-acids and peptides. There is no definite evidence that the administration of hydrolysates or amino-acid mixtures orally or by tube into the alimentary canal has any special value. Intact food protein by mouth is much more satisfactory.

The reason for employing amino-acid mixtures parenterally in place of, or along with, intact blood proteins in certain conditions is said to be based more on the necessity to sustain liver function and encourage a more vigorous nitrogen turnover than to build up a store of protein. To save body protein it may be wise to include all the amino-acids rather than to rely on the essential amino-acids plus glycine. Because of the difficulty of infusing sufficient protein and energy in the infusion fluid it is generally agreed that it is not possible to make good the requirements of the protein-depleted organism entirely by intravenous injection. It is not wise to inject fluid containing more than 5% of hydrolysate and 5% of glucose, but mixtures containing 8% of pure amino-acids can be given. Even with these concentrations it may take some four hours to inject 2,000 ml., and the patient may be very uncomfortable and demand rest. Some patients suffer actual distress.

Calorie requirements are inadequately met by these intravenous methods of feeding, and the recent work of Rose[1] indicates that with amino-acid mixtures or protein hydrolysates the deficiency is greater than would be expected with the equivalent of intact protein. It is held by some that for short periods of time the glucose intake can be safely limited to 100 g., the rest of the energy needs being met from the adipose tissue. The use of a stable finely divided emulsion of fat with a particle size of not more than two microns, such as that used by Geyer and his colleagues,[2] may prove to be a helpful method of meeting calorie requirements, but more corroborative evidence is required.

ERYTHEMA NODOSUM AND NODAL ERYTHEMA

The importance of tuberculosis in the aetiology of erythema nodosum is referred to in a paper by Dr. S. A. Doxiadis which appears elsewhere in this issue. Some aspects of the problem, however, remain obscure. It is possible that confusion results from casual clinical observation. The true eruption has a characteristic colour both in active and fading stages. The size and conformation of the lesions, the location, and the presence of tenderness and pain with pyrexia are distinctive, and if these features are absent it is doubtful if the diagnosis of erythema nodosum should be made. It was these characteristics which lent some support to the conception of a specific infective fever—nodal fever—now abandoned by most experienced physicians. A nodal erythema may accompany the eruption of a toxic erythema multiforme or may follow the administration of sulphonamides: it is sometimes seen in sarcoidosis and in other conditions, but it may be confusing the issue to regard such eruptions as erythema nodosum when they lack many of the distinctive features of that entity.

Erythema nodosum, in its classical form, commonly accompanies a recent infection, such as tuberculosis in the young—in which a primary lesion in the lung with unilateral hilar-node enlargement may recall the early phases of a syphilitic infection. The typical eruption following a streptococcal infection of the throat possesses the same features. While these are the commonest provocative causes in this country the condition is occasionally seen in association with deep-seated ringworm or with gonococcal, meningococcal, syphilitic, or other infections. The causative infections vary in different countries, but it seems that the typical attack of erythema nodosum indicates a peculiar and personal response to the presence in the skin of organisms derived through the blood stream from a recent primary focus of infection elsewhere. It is not merely a reaction to toxic products. To justify the analogy with syphilis erythema nodosum ordinarily should not recur. When it does recur it is generally in association with streptococcal infections of the throat, in which the immunity may be assumed to be only transient. Even so, much remains to be clarified. In chronic meningococcal septicaemia the eruption, characteristic in other respects, consists of small lesions scattered profusely over the limbs instead of a few large nummular lesions; it may continue to wax and wane over a period of months, suggesting the presence of an unusual static phase of sensitivity in the tissues. Whatever the explanation may be of the puzzling features of erythema nodosum, it is certainly desirable when the typical signs are present to seek for a causal organism, if necessary in the blood stream or in the skin lesions themselves. In this country care must be taken to exclude tuberculosis, especially in the young, by immediate overhaul and follow-up of the patient and by investigation of all contacts.

BEGINNING MEDICINE

About 2,500 students in Britain have now set off on the long road to a career that probably offers more diversity of interest than any other, a career, too, that is unlikely ever to be overcast by the shadow of unemployment, though in its initial stages the National Health Service has created difficulties rather than solved them for the man wanting to settle in clinical practice. All acknowledge that a wide general education is desirable for a medical student, and the foundations for this must be laid during the school years. But once embarked on the study of medicine few students find the time or energy to see far beyond the heavy textbooks that burden their knees for many years; and it must be confessed that of those who do some turn out to be interesting companions rather than pioneers in research. As Professor E. C. Dodds said[1] at the annual dinner of the Middlesex Hospital Medical School, the London schools are too narrow in their education, and we welcome his claim that the Middlesex School aims at keeping the basis of education as broad as possible.

The complement of a broad education is to be found in research, and Sir H. Cairns, in his inaugural address[2] at King's College, suggested that "nearly every young doctor should try his hand at one investigation . . . otherwise he will not find out what he is good for, nor will he appreciate the difficulties and labours involved in discovering new things." Every case contains some new thing that must be discovered, and if a knowledge of the textbooks helps the young doctor to clarify the patient's disorder quickly a training in research, even though slight, will make him more sensitive to the details peculiar to the patient that defy classification. Moreover, it encourages an inquiring habit of mind, and he learns that, in the words of Clement of Alexandria,[3] "the beginning of truth is to wonder at things."

Certainly the antithesis of this attitude is thinking "in moaning terms of what terrible conditions you are living under," against which Lord Bruce[4] warned the students when he opened the new term at University College Hospital. He emphasized the need for hard work, and medical students will not fail to appreciate the point when they examine the curriculum. He also adumbrated—as did Sir Hugh Cairns—a life of service rather than of place-seeking—an ideal readily accepted by young people, but which becomes more difficult to live up to as the passing years bring increasing opportunity to depart from it. The great fear is that the National Health Service, in spite of its name and aim, may not encourage the doctor to give of his best in service to the sick: in the words of Principal T. M. Taylor[5] when he addressed graduates at Aberdeen recently, "It will be an ill day for the community when the general practitioner degenerates into a filler of forms or an automatic machine dispensing chemical panaceas." Five or six years will pass before students now starting work seek in the practice of medicine that full and happy life that Sir Hugh Cairns wished them. Within that time the National Health Service will be over the experimental stage and, it is hoped, be better adapted to satisfying their aspirations.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

In this issue of the *Journal* we publish the first of a series of articles which will appear week by week under the heading of "Refresher Course for General Practitioners." Before the war we used to publish each week a special article of this nature for the general practitioner, but because of shortage of paper we had to discontinue this feature in 1939 until now. More paper has been available since the beginning of July, and it is hoped that no further restrictions will increase our difficulties in keeping a wide variety of readers informed on matters of special interest to them. "Any Questions?" was started in 1943 as an attempt to meet the need of the general practitioner for information on problems which concerned him in his daily work. It is hoped that this section of the *Journal*, together with the new Refresher Course, will continually revise for the general practitioner what is old and keep him fully acquainted with what is new in a manner that will be of practical use. We would welcome suggestions from readers for subjects that might be considered in the Refresher Course articles.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

THE ACUTE THROAT

BY

T. ANDERSON, M.D., F.R.F.P.S., F.R.C.P.Ed.

Lecturer in Infectious Diseases, Glasgow University

The complaint of "a sore throat" must be one of the commonest made to the doctor, and as the condition sometimes calls for urgent treatment the correct diagnosis is of some importance. Although the initial complaint focuses attention upon the throat it is necessary to remember two fundamental points: first, a throat infection may exist without sufficient pain to draw notice to its presence, which bears out the old clinical rule that examination of a patient—particularly a child—is not complete until the throat has been inspected; secondly, it should never be forgotten that the throat inflammation may be the local manifestation of some general disease.

Examination of the Throat

The examination of the throat is such a simple procedure that a description of the necessary manipulations is often taken for granted. Yet to obtain a proper inspection in a writhing youngster calls for tolerance and persistence on the part of the doctor. With patience and persuasion the co-operation of the child will often be fully attained, and where this course is possible it is much to be preferred. No attempt should be made to use force. The following points may be of assistance in difficult circumstances.

(1) *Holding the Child.*—When there is complete refusal to co-operate it will be necessary to pinion the child. The best method is to bring both arms across the chest and for an assistant to hold them there by catching both wrists in one hand. The assistant's other hand should hold the head firmly on the bed by placing the open palm across the forehead, the thumb to one side and the fingers to the other. In such a way the child may be held firmly and painlessly.

(2) *Opening the Mouth.*—Sometimes an unwilling child will hold the jaw tightly clenched. The spatula should then be inserted along the left-hand side of the mouth between the teeth and the buccal mucosa. Firm pressure inwards as far back as possible on the lateral aspect of the alveolar margin will usually result in the mouth being opened. The spatula can then be rapidly turned flat and passed on to the tongue.

(3) *Position of the Spatula.*—The spatula should be passed far enough into the mouth for the distal end to cover the posterior third of the tongue. Pressure should be downwards and forwards to enable a full view to be obtained of the fauces without forcing the tongue back into the throat, which not only blocks the airway but causes the child to "gag."

Diagnostic Points

When examining the throat the doctor must ask himself the following questions:

(1) *Is the Throat Acutely Inflamed?*—The soft palate, faucial pillars, tonsils, and pharyngeal walls should be carefully inspected for redness and oedema. The lesion may vary from a slight reddening of the palatal fringe, uvula, and anterior pillars to oedema so gross that the swollen uvula, palate, and tonsils almost close the faucial airway.

(2) *Is there an Inflammatory Exudate?*—This may be unilateral or bilateral, and three stages in its formation may be recognized. First comes the appearance of numerous discrete follicular flecks; secondly, there is a confluent, soft, loosely attached and rather pultaceous exudate; and, thirdly, one sees a confluent, firm, leathery membrane which is more or less firmly attached to the subjacent mucosa. Note that exudate is usually confined to the tonsillar surfaces, but membrane may extend on to the fauces, soft palate, or pharyngeal wall.

(3) *Is the Lesion Raised?*—When exudate or membrane is present its level relevant to the adjacent mucosa must be noted. The doctor must satisfy himself whether it is superimposed upon the mucosa or level with the adjacent surface, as if forming the base of a shallow ulcer.

(4) *Is the Membrane Discrete?*—It may be one continuous piece, or made up of numerous solitary areas with intervening normal mucosa.

The causes of a sore throat may be grouped under three broad headings—local virus infections, local bacterial infections, and general diseases.

Virus and Bacterial Infections

Influenza may start with a complaint of sore throat. In such cases the throat often shows little abnormality apart from some enlargement of the solitary follicles on the pharyngeal wall. There seems little doubt, however, that an upper respiratory virus infection can produce a generally inflamed throat with or without tonsillar exudate exactly similar in appearance to that of an acute bacterial infection.

Coccal Infections.—It is impossible to differentiate clinically between the various acute coccal infections. In general *Str. pyogenes* produces a severely inflamed and oedematous throat usually of sudden onset and associated with such great pain that swallowing is exquisitely sore. A tonsillar exudate is common with streptococcus, pneumococcus, or staphylococcus infections. This exudate may become confluent and closely simulate a false membrane, but it is more friable and white or yellow in colour. The associated lymph glands are enlarged and tender but remain discrete. In such cases the ear drums should always be examined. The drum-head may show a diffuse pinkness and slight lack of lustre that suggests a coccal tonsillo-pharyngitis.

Scarlet Fever.—A sore throat precedes the onset of scarlet fever, and the initial rash is often seen on the soft-palate, giving it a speckled appearance. The skin rash will usually confirm the diagnosis within 18–24 hours.

Pharyngeal Abscesses.—A peritonsillar abscess may develop on top of a pre-existing acute tonsillitis. The unilateral, tense swelling of the fauces and soft palate, pushing tonsil and uvula to the opposite side, is easily recognized, and the intense pain is a characteristic feature. Retropharyngeal abscess can be difficult to diagnose,

particularly in young children, because of the filling of the pharynx with mucus as a result of the difficulty in swallowing. The swelling produces a curious choking stridor which may be mistaken for laryngeal obstruction, but the latter produces a much "drier" stridulus with harsh cough. The fauces may show little inflammation in such cases, and should the character of the respiration have aroused suspicion there is only one course of action—persistence in obtaining a good view of the pharyngeal wall.

Diphtheria

A few years ago diphtheria would have taken first place in any consideration of the differential diagnosis of a sore throat. As a result of a reduction in incidence, largely due to active immunization, the clinician need not to-day regard it as occupying so high a place on the list. But it is well to keep two considerations in mind. First, in face of an appearance which suggests diphtheria a history of immunization should never encourage the practitioner to consider the diagnosis impossible. Secondly, it must be remembered that in the "immunized" subject a diphtheritic infection may produce an appearance indistinguishable from that of follicular tonsillitis. Typically, infection of a susceptible person with *C. diphtheriae* has an insidious onset and produces a mildly inflamed throat; the greyish membrane is "all of a piece" and often shows a slightly curled edge which may spread on to soft palate, faucial pillars, or pharyngeal wall when diagnosis is delayed. In general, the inflammatory reaction is limited to a zone surrounding the membrane and the diffuse bright redness characteristic of a streptococcal infection is seen less commonly. Pain is not a feature—indeed, it is often surprising to find how little pain may be associated with an easily recognized, severe diphtheria. Adenitis of the tonsillar glands, so often referred to in textbooks, is the mark of the severe or late case and is of little assistance in making an early diagnosis.

The most confusing appearance is produced by a severe *gravis* diphtheritic infection. The inflammation is intense and the soft palate and anterior aspect of the faucial pillars may be very oedematous and covered with a thin glairy mucus which is not unlike white of egg. This is, in fact, early membrane. The typical membrane may be slight or absent and the condition carelessly regarded as a quinsy. When diphtheria is epidemic the clinician should never hastily use a knife on what seems an acute peritonsillar abscess, for if the lesion is in reality diphtheritic incision greatly worsens the prognosis.

The diagnosis of diphtheria is never easy and even the expert can define no absolute diagnostic criteria. It should be more widely appreciated that modern diphtheria antitoxin is a highly refined and concentrated product, 8,000 units of which can be obtained in a 2 ml. syringe. When the clinician is in any doubt a dose of this magnitude is a safe procedure and will be adequate for most early cases. Serum reactions are now so rare as to be negligible.

Vincent's Angina.—This condition, like diphtheria, has an insidious onset, and as a rule produces little rise in temperature. The throat may simulate diphtheria in that the slough covering the ulcers suggests membrane formation. It will be observed, however, that the membrane is on a level with the normal mucosa and that it makes up several discrete, linear lesions separated by more or less normal mucosa. Although ulceration is seen in rare cases of diphtheria the lesion is continuous and does not consist of individual ulcers. In Vincent's angina the whole mouth is often unhealthy and the gums are inflamed and swollen —a further aid to diagnosis.

Sore Throats in Schools

In closed communities such as boarding schools, outbreaks of acute tonsillitis are most frequently streptococcal in origin. The cultures from the initial cases will usually decide which organism is responsible, and as a rule the swabs of throat and nose produce a heavy, almost pure, culture. Early diagnosis and isolation of those infected are the measures most likely to limit spread, but the high carrier rate which often accompanies such an outbreak may entail the isolation of a large proportion of the individuals. To begin with, all the residents must be subjected to a clinical examination at which particular attention is paid to ears, throat, and nose for the presence of otorrhoea, enlargement or irregularity of tonsils, or rhinitis. Those who show such abnormalities should have cultures taken from nose and throat and should be separated from the others; for it is this group which usually contains the carriers. The remainder should be inspected daily for a period of seven days and any individual showing signs of upper respiratory tract infection isolated at once. When cases continue to crop up among those who showed no abnormality of throat, nose, or ear two possibilities should be considered: first, that the epidemic is food- or milk-borne, and, secondly, that there is an unsuspected carrier remaining among the apparently healthy residents. In connexion with the latter possibility it is important to remember that the nasal carrier is the more dangerous.

When tracing the source of an epidemic which may involve a considerable number of persons the doctor should make early contact with the local medical officer of health and the nearest unit of the Public Health Laboratory Service. Precise knowledge of the organism involved is essential for any useful epidemiological work. For example, by determination of the serological type in streptococcal outbreaks it is possible to make more accurate decisions regarding the importance of a carrier or to assess the significance of milk or food in the spread of infections. Early consultation with the bacteriologist will ensure not only that he receives the right kind of specimens but also that he is able to proceed with the further definition of the pathogen involved.

Specific prophylaxis is only practicable in outbreaks of diphtheria, when combined active and passive immunization should be started. This consists of the injection of 500–1,000 units of diphtheria antitoxin into one arm and 0.5 ml. of A.P.T. (alum precipitated toxoid) into the other. Six to eight weeks later a second injection of 0.5 ml. of A.P.T. is given. Prophylaxis of streptococcal infections by the administration of sulphonamides is not advisable as a routine measure.

General Infections

Glandular Fever.—The anginose form of infectious mononucleosis produces a throat which may be indistinguishable from an acute coccal infection—indeed, the secondary invader is often a *Str. pyogenes*. Glandular fever is a systemic virus infection. Generalized lymphoplasia and splenomegaly will probably be present, but the diagnosis may be suggested by the sore throat suggestive of streptococcal tonsillitis appearing as a secondary manifestation after a few days of general malaise. In the usual streptococcal infection the sore throat is the first manifestation of an acute illness. There is little doubt that infectious mononucleosis now occurs more frequently than it did in the past. Accurate diagnosis depends upon the differential white cell count, which shows a mononuclear

leucocytosis and the characteristic atypical cells, and the demonstration of heterophile antibody in the patient's serum by the Paul–Bunnell reaction. This reaction is variable in the time of its occurrence and often becomes positive for the first time late in the illness. A titre of 1/64 is significant. Should the patient have received horse serum in the form of an antitoxin the bacteriologist must be informed, so that he may take steps to eliminate the resulting false-positive reaction.

Agranulocytic Angina.—The throat may show ulceration and membrane formation. There is, however, a characteristic lack of inflammatory reaction in contrast to the apparent acuteness of the lesion, and the soft palate, uvula, and fauces look pallid, soft, and jelly-like. The lesion is more frequently seen in adults; and a history will often be obtained of the habitual use of a drug containing the benzene ring. The amidopyrine group and, rather infrequently, the sulphonamides constitute the commonest aetiological agents. Diagnosis depends on lack of polymorphs seen on a carefully taken blood film. The film should preferably be made on cover slips to secure an even distribution of the white cells. If it is taken on a slide the most careful scrutiny should be made along the edges and at the end of the smear, for it is here that the polymorphs will usually be found.

Toxic Drugs.—Whether agranulocytosis is in fact a form of acute sensitization or not is still uncertain, but there is no doubt that an ulcerative stomatitis and pharyngitis without agranulocytosis can occur as part of a drug sensitization. The whole mouth is inflamed in this condition and as a rule there is some confirmatory evidence such as a rash. It is important to appreciate that the individual who has been sensitized to one drug is the more easily sensitized to others, and care should be exercised in the use of forms of therapy involving sensitizing drugs, such as aspirin and the sulphonamides.

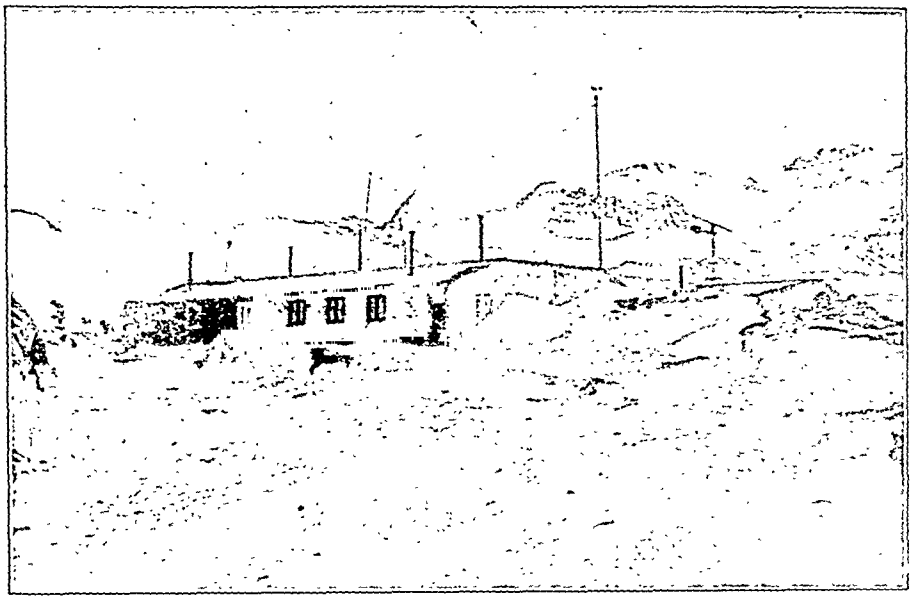
Other Conditions.—Acute leukaemia sometimes presents for the first time as an acute ulcerative tonsillitis. The child —for it is more frequently seen in childhood—usually appears ill and anaemic. There may be petechial skin haemorrhages, the spleen is often enlarged, and sternal tenderness is usual. Diagnosis can only be made after a careful examination of the blood.

Finally, in the adult, secondary syphilis should always be borne in mind as a cause of ulcerative tonsillo-pharyngitis. The presence of a typical rash may give a pointer to the correct diagnosis, but failure to respond to any form of treatment is often the first feature to make the clinician think twice about the diagnosis. Toxaemia usually appears mild in contrast to the severity of the local lesion. The Wassermann reaction will confirm the diagnosis.

Bacteriological Procedures

In the past, the focus of attention upon diphtheria resulted in the clinician tending to seek bacteriological assistance only when this diagnosis was under consideration. A carefully taken swab from the tonsillar surfaces, however, is of value in all throat infections and is particularly desirable in severe cases because of the guidance it may give in planning treatment. The swab must be taken before any form of chemotherapy is used. Most bacteriologists include a direct film in their examination of the throat swab, as well as culture on blood agar, Loeffler's slope, and a special medium to differentiate the organisms of diphtheria. The report may therefore supply valuable information in regard not only to diagnosis but also to prognosis.

Treatment



Antitoxin.—Although in many cases treatment will be guided by the results of the bacteriological examination, it is often necessary (and in a suspected case of diphtheria essential) to start treatment before the results of such examination are known. The dose of diphtheria antitoxin ranges from 5,000 to 100,000 units. Where the disease is suspected an intramuscular dose of 8,000 units will suffice. For the late, severe case when hospital admission cannot be immediately secured a dose of the order of 50,000 units will be required, and in such an event intravenous administration is particularly desirable. Such cases are best treated in hospital, however, and the practitioner will find that most fever hospitals are anxious to admit them even when the diagnosis is unconfirmed or in doubt.

Penicillin.—For the coccal infections and for Vincent's angina penicillin is the treatment of choice. It should be realized that the need is to secure an adequate local concentration of the antibiotic. The condition must not be thought of as a mere surface infection. Local therapy by lozenges and so forth is therefore completely inadequate and systemic administration in high dosage is indicated. If the aqueous solution is used a four-hourly dose of 100,000 units should be injected intramuscularly: procaine penicillin may be employed to advantage here, and two or three injections of 500,000 units during the first 24 hours may be followed by a lower dosage for the remainder of the time. For all throat infections due to susceptible organisms treatment must be continued for seven days to secure the best results.

Although there is no specific treatment for infectious mononucleosis the throat infection is usually due to either *Str. pyogenes* or Vincent's infection, and penicillin will prove effective. In agranulocytic angina, also, the administration of penicillin has greatly improved the outlook. Pentnucleotide should be injected intramuscularly. During the first 24 hours three or four injections of 5–10 ml. may be given, and thereafter the dosage will depend on clinical response. The administration of the antihistamine drugs might be considered, but the results have not been encouraging. In severe cases repeated small blood transfusions are valuable. The diet should be plain and contain no flavourings or adulterants, and care should be taken to avoid the use of any chemical which might have a sensitizing action.

Sulphonamides.—The administration of sulphonamides has been intentionally omitted from the treatment of the acute throat. The efficacy of these drugs has never been convincingly demonstrated in such conditions. Since they are undoubtedly toxic materials, carrying appreciable risks of sensitization, their administration is inadvisable, and in certain conditions may even be dangerous.

Finally, it must be pointed out that many mild throat infections clear rapidly and effectively without specific treatment. Gargling is so frequently indulged in by the patient before seeking advice that its continuation may be advised for its effect in cleansing the mouth. For those adults who can gargle, warm water with glycerin of thymol may also prove soothing to the throat. When pain is more severe the application of poultices to the neck, inhalations of friar's balsam, and, of particular value, the administration of aspirin powder, which is allowed to melt slowly in the mouth before swallowing—such measures are often adequate to secure rapid relief. The hasty rush for penicillin as a panacea for all cases is to be deprecated. It may do the patient little harm, but it can induce in the physician an easy optimism which may eventually cloud his whole judgment.

THE FALKLAND ISLANDS DEPENDENCIES SURVEY

BY

J. M. ROBERTS, M.B., B.Chir.

In 1943 the British Government decided to dispatch an expedition to the Falkland Islands Dependencies in order to maintain British sovereignty, which was challenged by Argentina and later by Chile. Since that time the continuous occupation of various Antarctic bases has been maintained by a succession of personnel. It was as one of the M.O.s in an annual relief party that I had the good fortune to stay on the Antarctic continent for 14 months. There were 30 in the party, including two M.O.s, one for each of the two large bases. These bases were far apart, the nearest to us being 120 miles away over open sea. Communication between them was maintained by radio, as it was impossible to reach another base except by the relief ship or by a sledge journey of 800 miles (1,300 km.) over unknown country. This journey was in fact done during the year as part of the survey programme, and it took four men 80 days to complete it.

At the beginning of November, 1946, we left London in a small Newfoundland sealing vessel built entirely of wood and powered by a Diesel motor and auxiliary sails. Our journey out was via Recife, in Brazil, Montevideo, and the Falklands, and it took us six weeks to reach Port Stanley, the capital and only large port. The Falklands are bleak, barren islands without trees, not unlike the Western Isles of Scotland. We arrived on Christmas Eve. Although it was midsummer it was very cold, and it snowed appropriately the following day.

After a fortnight's stay to check stores the parties sailed in two ships, one for the South Shetlands and the other for the South Orkneys. Sailing south-east, we took five days to reach the South Orkneys, where we relieved a party of four who had run a meteorological station for the past year. It was on this part of the trip that we encountered our first icebergs and pack-ice. For the most part the weather was extremely fine, and gave us that remarkably clear visibility characteristic of the polar regions. We could see the mountain peaks of the South Orkneys, over 100 miles (160 km.) away, standing so clearly on the horizon that it was not possible to estimate their distance. After two days in this neighbourhood, where we had our introduction to penguins, seals, whales, and other Antarctic fauna, we sailed south-west for Graham Land.

Our destination was Hope Bay, which lies at the north-east tip of Graham Land, at the foot of a glacier which descends from the inland plateau and down which there blows an almost continuous wind. The hut in which we were to live had been erected two years previously, and was partly buried in the ice. It was large and spacious, with double wooden walls and an aluminium-foil diaphragm between them. This bright surface helped to reflect the heat back into the hut, as well as providing two air pockets in the walls; its insulating value was equivalent to an inch (2.5 cm.) thickness of cork. The average temperature inside the hut for the year was 52° F. (11.1° C.), with a minimum of 32° F. and a maximum of 74° F. (0–23.3° C.), compared with the outside temperatures ranging from −14° F. to 49° F. (−25.5–9.4° C.), with an average of 22° F. (−5.5° C.). Inside the hut there was a large central living-room with small cabins leading off, an arrangement which had the disadvantage of cutting off what light there was in the summer. For nine months the hut was completely buried, however, so we had to use artificial light almost all the time. It has been said that cabins are undesirable for long periods of living in close proximity because men may go into hiding away from their companions. This never happened with us, and it was pleasant to have the little privacy cabins provided. Besides these cabins we had a laboratory and dark-room, a survey office, a kitchen, and a carpenter's shop. Outside there were two additional storage huts for reserve stocks. Lighting was by paraffin lamps and heating by an anthracite stove.

Nine men lived at the base. We had a duty rota, so that we each cooked for one week at a time and did the household chores one day in nine. Few of us had cooked before, but we soon learnt. Our diet was good, though mainly of tinned food. Fresh food consisted of penguins, which when stewed with onions can be very palatable, especially the chicks. Penguin eggs, which were very popular, were collected by the thousand and stored in flour. Shags and other birds were occasionally tried. Seals did not prove a great favourite, probably because they were so greasy. We did a certain amount of fishing through holes in the ice; the fish (*Notothenia*) were small, but very good when fried in butter. For fresh water we used blocks of snow, collected sufficiently far away from the base to be free from contamination due to dog excreta.

We supplemented our diet with 50 mg. of ascorbic acid daily, the tablets being on the table with the cruet. My predecessor had gone for two months without ascorbic acid and had developed early scorbutic signs. During the winter we noticed we were becoming easily fatigued with light work, and so we added vitamin A, 9,000 I.U., and vitamin D, 1,800 I.U., daily for a month; the supplements certainly seemed to have some benefit, although the reason is not entirely clear.

We were issued with ample supplies of tobacco and cigarettes, and all of us became heavy smokers by the end of the year. As with the food, we divided all our stocks in two, so that if we failed to be relieved we should be able to last another 12 months.

There was an issue of rum, whisky, and gin which was adequate for our needs, but beer entailed the risk of being frozen and breaking the containers. We had a local rule that we drank only on Saturday nights, birthdays, half-birthdays, and special feast days, such as midwinter's day.

I have been often asked, Did we get bored? We did at times, but there was plenty of work to do. Three-hourly "met" observations had to be made, recorded, and transmitted by radio. We had the dogs to feed, which meant days of seal-hunting, and our sledges had to be kept in repair. Our stock of books was widely selected, and games such as darts, draughts, and "nine men's morris" were also popular. Against boredom of our companions I think each of us built up his own defence mechanism: there was a strict regulation that stories were not allowed to be repeated more than once a month.

During the year survey parties left the base for long sledge journeys. Usually there were two men to one sledge, which carried their food and tent and was pulled by a team of 13 dogs. The distance covered in a day varied greatly with the type of country and weather encountered, but the average speed was 4 m.p.h. (6.5 km.p.h.). One party travelled nearly 60 miles (95 km.) in 24 hours, while another did 200 yards (180 m.) in the same time, as a blizzard sprang up just as they had struck camp.

Sledge runs were usually made for an hour at a time, as we found the dogs would go better if they had regular stops. These dogs, 40 of which were brought from Greenland, were the best companions one could wish to have. Their social habits made a fascinating study, and, though fierce among themselves at times, they never bit any of our party. From the original 40 they increased their numbers up to 120 by the end of the year.

Throughout the year the general health of the party was excellent, and we were completely free from colds, unlike other expeditions who reported that they caught colds every time they opened fresh bales of clothes which had been left undisturbed from the time they were packed in England. We did get colds when the relief ship arrived, however. We had one or two infected cuts from handling seal blubber, but I do not think these were comparable in severity with the spek finger of the northern sealers. One case did lead to chronic ulceration of the arm and axilla, the pathology of which was uncertain. Frostbite and snowblindness, the two enemies of the polar regions, were never severe, mainly because we took care to avoid them. Carious teeth required frequent attention, which was usually given in the form of a temporary stopping, though occasional extractions were called for. The only major casualty was a man with two slipped intervertebral disks, which kept him in bed for over eight weeks and which it was found necessary to remove on his return home.

THE PRISON POPULATION

ANNUAL REPORT OF THE COMMISSIONERS

The average daily prison population in this country is around 20,000, a considerable increase on the 13,000 of five years ago. Populations of the present order have not been known since 1911. The number of receptions on conviction—which is always greater than the number of different persons received in prisons, since some men after finishing one sentence are sent to prison again in the same year—was 33,566 in 1947. Women account for about one in ten in these totals. Well over half the offences for which persons are received in prison are larceny and burglary and housebreaking. Sexual offences by men accounted for 1,053 receptions in the year under review, and offences of violence, including murder and manslaughter, for 728 receptions of men and 81 of women. About half the male prisoners and 70% of the female prisoners were sentenced for not more than three months.

In the Report of the Prison Commissioners just published[1] the narrative as a whole relates to 1948, but the statistics mainly to 1947. It sets out the principal changes which the Criminal Justice Act will bring about in the prison and Borstal systems, but it reserves until the next report any account of the measures taken to meet the new and complex responsibilities arising under the Act. The restrictions on the imprisonment of young persons may be expected to lead to a decrease of young prisoners and an increase in the Borstal population. In 1947 the number of persons between the ages of 16 and 21 found guilty of indictable offences was 19,331, the lowest since 1940, and of the 2,912 persons in this age group sentenced to imprisonment 790 had not, so far as was known, been guilty of any offence previously.

It is not easy to draw any firm conclusions on the problem of recidivism from the statistics given in this report. They include the numbers of convicted prisoners against whom previous offences were known, but the factors affecting such figures over a long period of years are so many and variable that the Commissioners themselves withhold any comment. Of the convicted prisoners in 1947, 71.5% of the males and 67.5% of the females had previous proved offences. Indeed, 392 men and 43 women had over twenty previous convictions. It should be added that from these figures imprisonment for drunkenness is excluded, the reason being that if it was included it would overweight the figures on the female side. Thus in the year under review 1,115 men and 349 women were imprisoned for drunkenness, but while the first figure represents only 3.7% of the total number of male convicted prisoners the figure for females represents 10%. The numbers imprisoned for drunkenness in 1947 were only about one-fifth of the total for 1938. Comparisons with a much earlier period are vitiated by the fact that not until the Criminal Justice Administration Act, 1914, was time required to be given for the payment of fines, and therefore in earlier years there was a very large transitory prison population.

The Borstal System

The change of name from "Borstal detention" to "Borstal training" is welcomed. The Commissioners point out that Borstal is in the "news" when things go wrong, but good behaviour has no news value. The conduct of the Borstal boy is on the whole satisfactory, and often very good, although it has to be admitted that nearly a thousand boys absconded or attempted to abscond during the year. It is not a simple statistical matter to find out whether Borstal boys make good. From the figures given it appears that more than half those discharged are not re-convicted, but only intensive social research based on personal histories over a long period can show how many of these young men have become useful members of society. The Borstal population consists of about 3,000 boys and rather more than 200 girls.

The most immediate effect of the introduction of the National Health Service was a large increase in the number of prisoners receiving dental and ophthalmic treatment. It has also been possible to arrange in the case of Borstal inmates for operations to be performed at local public hospitals. Arrangements have now been made, and are being extended to all prisons, for cases of venereal disease to be treated by venereologists serving in local clinics. In the case of small prison establishments prisoners are sent to the public clinic as often as may be necessary, and in larger ones venereologists hold their clinics in the prisons. Other National Health Service facilities of which full use has been made are those in connexion with tuberculosis, though in this case the change has been no more than administrative.

This greater use of public services, while it has not lessened the prison medical officer's responsibility for the health of all prisoners in his charge, has to some extent freed him for the undertaking of certain special investigations. The report gives a list of researches which have either been completed or are in progress.

Psychiatric Studies

An investigation is being carried out at Wormwood Scrubs and Wandsworth, in collaboration with members of the Maudsley Hospital staff, on prisoners who are psychopathic personalities and who consent to undergo the tests. The group

ANAESTHETICS

'TRILENE'–in addition to its use in analgesia–is employed with success for the production of a light plane of anaesthesia. Contra-indications are few, and recovery is rapid with no unpleasant after-effects.

Containers of 250 and 500 c.c. Crushable ampoules of 1 c.c. in boxes of 5; ampoules of 6 c.c., boxes of 1, 5 and 25.

'KEMITHAL' SODIUM is a highly efficient ultra-short-acting barbiturate used for induction and surgical anaesthesia of short or prolonged duration. Notable features of its use are minimal respiratory depression and a consistently good post-operative recovery, free from vomiting, restlessness and protracted depression.

Ampoules of 1 or 2 grammes, with or without distilled water. Containers of 5 and 25.
Ampoules of 5 grammes, without distilled water. Containers of 5.

Other anaesthetics and analgesics include: 'Avlon' brand Chloroform, Procaine, and Pethidine (with and without Hyoscine).

'An extremely potent oral œstrogen'

At the time of the menopause many women suffer from distressing subjective symptoms which are due to endocrine imbalance caused by failing ovarian function. Prompt relief may be obtained by the judicious administration of a potent, well-tolerated œstrogen.
Ethinyl œstradiol is eminently suitable for such a purpose. It is the most active œstrogenic substance known, is effective orally and, since it is a simple derivative of the natural ovarian hormone, is less likely than the synthetic œstrogens to cause unpleasant side-reactions. Further, ethinyl œstradiol (available as 'Estigyn') has a predominantly pituitary-inhibiting action, which renders it particularly effective in relieving the disturbances of the menopause.

For effective relief of

nasal congestion

IN head colds, sinusitis, etc., nasal congestion not only contributes to the general discomfort of the patient, but also often complicates these conditions by interfering with normal ventilation and drainage. Nasal congestion is effectively relieved by 'Benzedrine' Inhaler. Its action is immediate; the effect lasts a full hour. It does not interfere with ciliary activity, and secondary reactions following its use are virtually negligible.

Children welcome the novelty of 'Benzedrine' Inhaler and show none of the hostility often associated with 'nose drops'.

A better means of nasal medication

is limited to male offenders between 18 and 40 in whom there is no family history of epilepsy. A similar number of offenders whose personalities are regarded as normal are to be used as controls. Research into the endocrinological aspect of cases of psychopathic personality is in progress at Bristol and Leyhill (known in the Press as the "prison without bars"). At Holloway an investigation into the causes of child neglect by women has recently been completed. Studies at Wakefield under the principal medical officer include the whole population of the prison. From the history and the physical and psychiatric examinations and tests a profile is constructed which gives at a glance the principal features in the early home circumstances, the civil state, the criminal career, and the mental condition of each prisoner received. To provide for the psychological treatment of prisoners serving short sentences arrangements are being made for psychiatrists employed by the regional hospital boards to attend wherever possible at the larger local prisons. In selected cases treatment begun while in prison will continue under the same therapist after release. So far it has been possible to give effect to this only in one of the regions. Prisoners treated at local psychiatric centres during their sentences, largely owing to the sharp contrast between the clinic and the prison, rarely avail themselves of whatever arrangements are made for treatment after release. On the other hand, if a prisoner is visited by a therapist in prison the likelihood of his continuing treatment after release is increased.

Prison Medical Officers

The recruitment of medical officers to prisons does not keep pace with the demands of the service. Notwithstanding the increased opportunities for research, the requirements of the Criminal Justice Act, involving a sharp increase in the number of medical reports asked for by the courts, and prolonged investigations in preparing such reports, together with the necessary attendance at court, will add considerably to the prison medical officer's duties. The report states that "there can be little doubt that it will be difficult to maintain the standard of work or embark on further research unless a substantial increase in the rate of recruitment takes place." Prisons, too, are affected by the nursing shortage. The recruitment of female nursing staff to prisons continues to decline, and a return to prison-trained hospital staffs may have to be considered.

AMINO-ACIDS AND PROTEIN HYDROLYSATES

A RECENT SYMPOSIUM

A symposium on "Amino-acids and Protein Hydrolysates" was held in London on September 28–30 by the Food Group of the Society of Chemical Industry. While some of the papers were on the purely chemical and physico-chemical aspects of amino-acid preparation and isolation, several speakers discussed the nutritional and clinical aspects of protein and amino-acid nutrition and metabolism.

In the course of a comprehensive opening address to the conference Professor E. C. DODDS drew attention to the work of Dent and Schilling,[1] who had examined by means of paper chromatography the portal blood and sometimes also the jugular blood and the urine of dogs after the feeding of various proteins such as casein, casein hydrolysate, ground beef, and human serum (the plasma proteins being removed first by ultrafiltration). No peptides had been found in the blood after any of these proteins were fed. After feeding human albumin certain ninhydrin-reacting substances decomposable by hydrolysis were found in the urine. When dog plasma protein was fed to dogs there was no appreciable change in blood amino-acid levels, though the protein disappeared from the gut. It was presumed from this that under the condition of experiment the dog plasma had been absorbed intact. This finding opens up wide and interesting fields of exploration. Dent[2] has also shown in recent studies that in at least five human diseases—namely, acute yellow atrophy of the liver, the Franconi syndrome, cystinuria, phenyl ketonuria, and multiple myelomatosis—urinary amino-acid excretion is abnormal and characteristic of the disease. Professor Dodds referred to the work with isotopic tracers by means of which the rapidity of turnover of the proteins in the liver had been demonstrated: in rats half the protein is degraded and resynthesized within six days.[3] He also described how certain amino-acids had developed into therapeutic agents, two examples of these being methionine and glutamic acid.

Amino-acids as Therapeutic Agents

The importance of methionine in the body depends on two factors: it contains the element sulphur and a labile methyl group. Because of these two characteristics it plays an important part in the detoxication and lipotropic functioning of the liver. Several workers have shown that methionine can apparently improve cirrhotic conditions of the liver.[4–8] There have also been reports on the use of methionine in the treatment of infective hepatitis, but in this condition it has not been found uniformly successful. Methionine has been used successfully in the treatment of a patient with subacute necrosis,[9] and Eddy[10] reported that in trinitrotoluene and carbon tetrachloride poisoning it gave good results. Glutamic acid has been shown by Weil-Malherbe[11] to be of importance in the metabolism of brain tissue. Zimmerman, Burgemeister, and Putman[12] administered glutamic acid to children and adolescents with convulsive disorders, some of whom were also mentally retarded. They found what they considered to be a significant improvement in the results of intelligence tests.

In 1938 Fildes[13] made the interesting observation that indoleacrylic acid inhibited the growth of *Bact. coli*, and subsequent work showed that 4-, 5-, 6-, and 7-methyltryptophans all possessed the power of inhibition.[14] These observations have been extended to other synthetic amino-acids: Beerstecher and Shive[15] found that β-2-thienylalanine was strongly inhibitive, and Elliott, Fuller, and Harington[16] have shown that certain β-derivations of alanine have antibacterial properties. New chemotherapeutic agents may be found by continuing the study of the metabolism of bacteria in the manner that Woods[17] initiated when he discovered that the sulphonamides compete with *p*-aminobenzoic acid for an enzyme system necessary for bacterial growth.

Amino-acids and Cancer

The observation[18] in 1939 that dextro-rotatory glutamic acid (the presently accepted unnatural form) could be isolated from the protein of malignant tumours was contested by Chibnall and his colleagues,[19] but it was reaffirmed this year by Kögl as a result of tracer studies.[20] Professor Dodds pointed out the importance of such an observation as possibly giving a clue to the reason for the independent continuous reproduction of the cancer cell as compared with the self-limiting reproduction of the non-malignant cell. However, it would appear necessary for considerably more positive evidence to be produced before the presence of a dextro-rotatory acid can be regarded as a characteristic of the protein of malignant tissues.

Apart from the part played by individual amino-acids, there is evidence that they form certain conjugates either with other amino-acids or with chemical groups and that these compounds are of special importance in the body—for example, folic acid

(pteroylglutamic acid). Synthetic products which are modifications of this amino-acid derivative are being used extensively in the treatment of cancer, and typical examples are alpha-methopterin and aminopterin. Great improvement has followed the administration of these substances in certain cases of leukaemia and Hodgkin's disease, but the results appear to be of a transitory nature. Whatever their ultimate position in cancer therapy will be, they are of very great theoretical importance.

Professor Dodds also drew attention to the point made recently by Sir Robert Robinson—namely, that a number of amino-acids can be regarded as building-stones not only for proteins but also for alkaloids. Thus ornithine may be regarded as one of the originating substances of some coca bases.

Protein Composition

Dr. Kenneth Bailey described some features of the amino-acid composition of proteins and pointed out that exact amino-acid analyses, such as Sanger's work on insulin, were of great use in determining the make-up of proteins but did not disclose much about their physico-chemical nature. In nutrition research determination of the amino-acid make-up of the mixed proteins of the individual foodstuffs was of value. Dr. Bailey reported that when he plotted reliable data, such as Tristram's on amino-acid composition, in the form of a histogram he found that the essential amino-acids fell within a much narrower frequency range than did the dispensable amino-acids. This would indicate that with the exception of incomplete proteins such as zein and gelatin most proteins have relatively constant proportions of those amino-acids which are found to be essential in the diet. Dr. Synge also emphasized the uniformity of the mixtures of amino-acids encountered in nature. He thought this should lead in the near future to a systematization of procedures for determining amino-acids, though much further work was necessary on the more complicated substances such as peptides. Dr. Neuberger referred to the changed outlook on the chemistry of the proteins which had taken place between the two world wars, and Dr. Tristram and Dr. Barton-Wright described the chemical and microbiological methods for the determination of the amino-acid composition of proteins.

Dr. Lea drew attention to the amino-acid or Browning reaction which occurs in aqueous solution, or in the comparatively "dry" state, between protein or amino-acids and sugars to produce changes in odour, flavour, colour, solubility, etc. The net effect of this is sometimes desirable and purposely sought, but in other instances is highly undesirable, even sometimes amounting to a loss in the biological value of the protein. Investigations with dried milk and other foodstuffs have shown that the most rapid of the chemical reactions is a combination of the reducing sugar with the free amino groups of the protein. Since these are very largely the ε-amino groups of the lysine side-chains a nutritional deficiency of this amino-acid may result. The use of hydrolysed protein and of amino-acids as flavouring agents was considered by Dr. Rees: in small amount (0.05–0.5%) the monosodium salt of glutamic acid is said to improve and enhance the flavour of the food.

Dr. Dyson and Mr. Bavin described the careful methods which are necessary for the preparation of an enzymic hydrolysate of casein so that it is sterile, pyrogen- and anaphylactogen-free, and does not cause blood-pressure changes on administration. Precautions are also taken to reduce the deposition of tyrosine. These speakers also drew attention to the work of Geyer and his colleagues[21] on the usefulness of a fat emulsion in which the particle size is not more than two microns. This emulsion can be autoclaved and administered in 30% concentration without the risk of embolism.

Protein Metabolism

Dr. D. P. Cuthbertson reviewed the comparative physiology and pathology of amino-acid and protein metabolism and drew particular attention to Rose's[22] latest account of his human experiments on amino-acids and hydrolysates of protein for the maintenance of nitrogen equilibrium in man. The latter had found that for maintenance the eight amino-acids, *l*-tryptophan (0.25 g.), *l*-phenylalanine (1.10 g.), *l*-methionine (1.10 g.), *l*-leucine (1.10 g.), *l*-isoleucine (0.70 g.), *l*-valine (0.80 g.), *l*-threonine (0.50 g.), and *l*-lysine (0.80 g.), are necessary (his assessment of the minimum daily requirements of each for the adult is indicated in parentheses, but he recommends as the daily intake twice these amounts.) For the growing human organism histidine and arginine are probably necessary, and it may be that some of the amino-acids thought at present to be dispensable may be necessary if the synthetic capacity is liable to be overtaxed, for the human requirements of amino-acids for pregnancy and lactation or in different forms of illness are still not known. Rose has found disconcerting differences in the minimum amount of amino-acid required by different individuals under comparable experimental conditions. With certain amino-acids the results are consistent, with others there may be as much as a 100% difference. While the role of methionine, cystine, and vitamin E in the prevention of experimental acute liver necrosis is still not very clear, progress is being made. The recent observation by Patt and his colleagues[23] on the protective action of cysteine on rats exposed to *x*-radiation is also of considerable interest.

Dr. Cuthbertson stressed the relative constancy of the intake of protein in dietary surveys of all classes and at all energy levels in temperate climates when the protein is expressed as a percentage of total calories. This occurs at all ages from one year onwards. All the normal physiological states appear to be covered when the protein intake lies between 11 and 14% of the calories, the higher values being related to growth, reproduction, and lactation. The speaker also discussed protein insufficiency, the effects of trauma and infection, and the requirements for convalescence, as outlined in a recent paper by him in this *Journal*.[24]

JUVENILE DELINQUENCY

FIELDS FOR FUTURE RESEARCH

A conference on the scientific study of juvenile delinquency was held on October 1 at the Royal Institution, London. It was convened by the National Association for Mental Health, the Royal Medico-Psychological Association, and other bodies, and was opened by the Earl of Feversham, president of the National Association of Probation Officers. Introductory remarks were made by Miss Cecily Craven and by Mr. Alec Rodger, honorary secretaries respectively of the Howard League for Penal Reform and the British Psychological Society. The conference was attended by representatives of Government departments, local authorities, the magistracy, the Church, educational bodies, and voluntary and youth organizations. The Home Secretary, in a message, said that the Home Office was considering the question of Government assistance for research.

Limits of Present Knowledge

Dr. J. D. W. Pearce, medical co-director, Portman Clinic (*Institute for the Scientific Treatment of Delinquency*), said that much of the work on this subject had been handicapped by lack of knowledge of scientific method and by rather woolly recording. A difficulty had been the absence of adequate control groups, but a great deal was known about the intelligence and educational attainment of the juvenile delinquent. Many delinquents were skilful and therefore were never caught, so that it might be that the intelligence of delinquents in general was ranked too low and more nearly approximated to average intelligence. Something was known also of the problems of psychopathic personality and temperamental instability, though there was still disagreement about how far the latter was constitutional or acquired. Electroencephalographic studies were helping to throw light on conduct disorders. Sir David Henderson had reported cases in which cerebral surgery in adult criminals had brought about a remarkable change in character; but these things were in their infancy. Something was known about the psychological mechanism involved in delinquency, not only in the individual but in the group. Clinical types could be identified and treatment prescribed: prescription might be relatively easy and administration more difficult. Individual psychotherapy based on sound analytical

training had revealed a great deal about aetiology. Facilities for observation, care, treatment, selection, grouping, and experiment, however, were inadequate. Rarely was delinquent conduct to be explained by a simple cause; nearly always there were many factors concerned.

Dr. H. MANNHEIM, reader in criminology, London School of Economics, agreed that in this matter of the young delinquent all too often half-baked truths and slogans took the place of exact scientific knowledge. The weakness of most investigations—Sir Cyril Burt's *The Young Delinquent*, first published in 1925, was an exception—was that they were exclusively based on court cases; consequently very little was known about delinquents who did not appear in court or about non-delinquents who in essential characteristics resembled delinquents. Non-court cases ought to be included in any study. Dr. Mannheim, at the end of his paper, asked whether the research done so far had been of any practical use to anybody—to the legislator and administrator or to the practical worker in the field. Sixteen years ago Sir Alexander Paterson wrote a paper entitled, "Should the Criminologist be Encouraged?" He was not sure of the answer, apparently, but the greatest encouragement the criminologist could desire would be a favourable answer to the question he had put.

Personality and Social Factors

Dr. JOHN BOWLBY, director, Child Guidance Department, Tavistock Clinic, mentioned three false assumptions by which research in the past had been vitiated: (1) that delinquency was clear-cut and distinct from other forms of behaviour; (2) that there was no necessity for qualitative distinctions; and (3) that the problem could be studied by concentrating on cases brought into court. Little light would have been cast on the problem of malnutrition if physiologists and physicians had not studied large samples of the population irrespective of whether they came into hospital or not; many most informative studies on nutrition had been made outside the clinic. It was only a specially selected group of delinquents who came into court. Public-school boys rarely came before juvenile courts. Was that because they never stole or because their parents and schoolmasters dealt with them in some other way?

Individual susceptibility to adverse influences was clearly a psychological problem. Why was it that some individuals grew up more susceptible to antisocial influences than others? Research in child development suggested that it depended on the relation which the child had with his parents in his early years. Two factors specially common in the history of persistent delinquents were prolonged separation (not less than six months) of the child from his mother during the first five years, and the child being unwanted by parents who were themselves unstable and unhappy. Blanket generalizations regarding "family atmosphere" and "broken homes" were as useless as would be similar generalizations about diet in research on nutrition. A thorough analysis of the young child's social "diet" was required for a study of antisocial attitudes.

Dr. Bowlby suggested that a worth-while project in this field of research would require from 12 to 20 professional workers, a corresponding number of clerks and secretaries, a period of five or eight years, and an expenditure of £15,000 to £20,000 a year. The sum spent on research on nutrition, which had paid such splendid dividends, far outstripped these totals. "The whole of medical and sociological research could be financed for a decade out of the sums spent on the development of the Brabazon."

Professor T. S. SIMEY, Department of Social Science, University of Liverpool, said that it was not justifiable to consider the characteristics, behaviour, and treatment of the delinquent as an isolated individual. Not even the adult criminal, still less the young offender, should be considered as something essentially "different" merely because he had been found guilty of breaking the law. Crime was the result of dysfunction within the society in which it took place.

Call for a Central Research Body

A central authority to initiate, execute, and co-ordinate research and to provide technical advice was called for by Professor Simey, and the same idea was taken up by the last contributor to the symposium, Dr. DENNIS CARROLL, medical co-director of the Portman Clinic, who said that there was a case for setting up a "Delinquency Research Council," possibly covering social research in general. There was no shortage of suitable experienced individual advisers, but for the many highly expensive and complicated researches required such a central authoritative body would have the advantage of commanding enough money and enough general support to make the practical task really effective. For example, there was need for a thorough survey of probation to discover the best criteria for placing an offender on probation and the best form of probationary care. Many other things could be discovered at the same time, and some of them would quite likely lead to the development of special educational systems for certain ascertainable types of offender, such as the potential recidivist, the young psychopath, or the unstable dullard.

Dr. Carroll mentioned some generally unchallenged statements, such as that parental control had diminished, that religious faith had declined, that boys' clubs were a major weapon in preventing delinquency—all of which were plausible and probable, but none of them supported by studies which could withstand scientific criticism. Much was heard about defective control of children, but it was not always the fault of the parents; on the religious question it was very hard to avoid subjective bias; and as for boys' clubs, a survey in 1942, *Young Offenders*, by Carr Saunders and others, gave information which cast some doubt on the general assumption, though it did not settle the issue. It was not that these assumptions were necessarily wrong, but they were accepted without proof. Incidentally Dr. Carroll suggested that the Press might try to design a system of crime reporting which would have crime prevention as its main object. Finally he laid stress on the importance of keeping such records and statistics as would make it possible for others dealing with delinquents to know exactly what had happened.

MEDICAL PROTECTION SOCIETY

ANNUAL MEETING

The annual meeting of the Medical Protection Society (formerly the "London and Counties") was held at Victory House, Leicester Square, on September 28. Sir Ernest Rock Carling, who presided, referred with regret to the loss during the year of three vice-presidents—Dr. G. M. Stoker, Sir Edmund Spriggs, and Professor Harry Stobie. He welcomed as new members of Council Mr. H. L. Hardwick and Dr. J. H. Hunt.

The relation of the Society to the other two defence societies, Sir Ernest Rock Carling continued, was fruitful in many directions. On the question of sterilization the three societies had jointly sought the opinion of counsel, which was that the only circumstances in which a sterilizing operation could be rightfully performed were those in which the operator honestly believed upon reasonable grounds that such an operation was necessary to preserve the life of the patient or to avoid serious injury to his physical or mental health. A doctor should make sure that such danger existed, should obtain where possible a second opinion, should make plain to the patient the results of the operation, and obtain his consent in writing, freely given without undue influence by others. In such circumstances both surgeon and patient would be safe from any suggestion of illegality.

The Society did a great deal more for its members than appeared in the pages of its report. In addition to the cases which came before the Legal Committee, something like 40 applications a week were received for assistance, many of them in matters which, strictly speaking, were not within the Society's scope. The Society had been glad on several occasions to help—although it could not represent—members at hearings before medical or dental service committees under the National Health Service, as well as to appear for members at appeals. It was extremely important that the Society should receive the earliest possible information of any charge brought against a member.

A circular was issued by the Home Office forbidding the payment to salaried officers in the National Health Service of allowances as professional witnesses for attendance at court. The Society had taken the opinion of counsel, who advised that certain paragraphs of the Home Office circular were conflicting and had no legal force. A suitable case coming before an assize court, counsel was instructed to raise the matter of fees, and the judge ruled that the direction in the Home Office circular was too narrow. An intimation had now been received from the Home Office that the part of the circular which laid down these restrictions had been withdrawn.

An influential member had written to the Society to suggest that its insistence upon *x*-ray evidence in all cases of injury and the like was inexpedient in view of the cost and present shortage of *x*-ray films, but Sir Ernest Rock Carling, while mindful of economy, thought it would be a very unfortunate thing if such evidence were not obtained. It was the legal profession rather than the medical which required education in this matter. Other precautions which the experience of cases had emphasized during the year were the necessity for extreme care in the administration of intravenous fluids and the perennial matter of the checking of swabs. He was inclined to think that some authoritative body ought to undertake a survey of the methods of checking swabs, their recording and recovery. The Society had taken up the question of hypodermic needles broken in the course of an injection, and he thought that on every occasion the metallurgist had reported an actual defect in the needle.

Sir Ernest Rock Carling was unanimously re-elected, as were the retiring vice-presidents and other officers. The annual report, which was adopted, embodied a statement by the solicitors (Messrs. Le Brasseur and Oakley), who wrote:

". . . should it have been in the mind of any member that the advent of this [National Health] Service would render the protection of your Society unnecessary, the experience of the first year of the Service has most emphatically proved the contrary. . . . New risks have been created and new problems have arisen calling for advice. Our experience and that of the Society has been that more applications have been received from members for advice and guidance than at any previous time in the life of the Society. A new bureaucracy has been created, and though the various committees and tribunals are all under the Minister of Health the Minister has shown in our present experience a decided disinclination to interfere with the dicta of such bodies excepting in cases where there is a right of appeal."

Arab refugee children from Palestine in the Middle East area are being vaccinated against tuberculosis by Scandinavian medical teams, under the sponsorship of UNICEF, the United Nations International Children's Emergency Fund. Some 250,000 refugee children under 18 in Lebanon, Syria, Transjordan, and Palestine are being tuberculin-tested, and all who require it will be vaccinated to protect them against the disease. Tuberculosis has been a cause of increasing concern to medical officers in the refugee areas. There are hundreds of thousands of refugees in North and South Palestine and surrounding countries, living in tent camps, overcrowded and devastated villages, many in caves, shanties, and other improvised means of shelter. Five special vaccination teams, consisting of one doctor and four nurses each, were recruited in Denmark, Norway, and Sweden. These are skilled vaccinators, most of whom worked for some time in the joint UNICEF-Scandinavian International Tuberculosis Campaign in various countries of Europe. It is expected that they will complete the vaccinations of the refugees in about three months. Vehicles and medical supplies for the refugee vaccination programme were provided by UNICEF. The vaccine is being delivered regularly by air from the Danish State Serum Institute in Copenhagen to Beirut, Lebanon, for subsequent distribution to the vaccination centres. The vaccination programme is conducted in close co-operation with the medical officers of UNRPR (United Nations Relief for Palestine Refugees) and of the three agencies which are caring for the refugees: the League of Red Cross Societies, the International Committee of the Red Cross, and the American Friends Service Committee (Quakers). Dr. Mogens Fog-Poulsen, of Aarhus, Denmark, is chief of the mission.

NEW HUNTER DOCUMENTS EXHIBITED

The Hunterian Society held a cocktail party, instead of its annual dinner, on October 6, and displayed an interesting collection of historical relics which are in the curatorship of Mr. C. Robert Rudolf. Chief among them were legal documents relating to John Hunter and his eldest son, John Banks Hunter, which recently came to light and were displayed for the first time. John Banks Hunter was born eleven months after John Hunter's marriage and received his second name after his father's friend, Joseph Banks, the naturalist. His life is something of a mystery. He entered St. John's, Cambridge, but left without a degree and joined the Army. After serving for a number of years he bought himself out and went to live at Toulouse. There appears to have been some trouble, for Mrs. Hunter wrote in 1810 of "my poor unhappy son," and another relative refers to the eccentric cousin.

The new documents shown at the Hunterian Society concerned the earlier wills of this son, the first being the original sealed will of "John Banks Hunter (John Hunter Junior) Ensign in the 2nd Battalion Royal Regiment of Foot, dated July 18, 1794." The testator left his property to his mother, or, if she was deceased, to his only sister Agnes. There was a note in the will: "Add the freedom to Geo. Bristow"—a slave kept by Hunter, the provision for whose release is referred to in the next will, dated December 12, 1804. The second will is very similar to the first; it is interesting that J. B. Hunter should have used the crest of his father (then dead eleven years) to seal it. Later, twelve years after his mother's death, J. B. Hunter made another will, of which a photostat copy was shown, leaving his property in Scotland to his sister, but his personal estate to a friend in Toulouse. The absence of any reference to a wife seems to confirm what is stated in the *Reminiscences* of Elizabeth, daughter of Matthew Baillie, written 1866–8 (Royal College of Surgeons MSS), that J. B. Hunter died unmarried.

The new documents relating to the estate of John Hunter himself were a lawyer's copy of his will, and two drafts of a power of attorney by the son and heir on his going to Corsica. Among other recent acquisitions were snuff boxes belonging to John Hunter and also to a Dr. John Hunter who practised in the Minories and is stated to have been a friend of his illustrious namesake. There were also shown an original Laennec stethoscope, whose proportions were exactly those of the instrument illustrated in its inventor's *Traité de l'Auscultation Médiate* (Paris, 1818), and a tinted silhouette of Jenner.

The rest of the exhibition was devoted to the history of the Society, including a letter from Mr. T. J. Armiger, assistant surgeon to the London Hospital, who suggested the Society's foundation, and a reply in verse by the present Poet Laureate to an invitation from the Society. The Society's custom of holding an annual dinner was instituted during the presidency of Dr. Benjamin Robinson; a manuscript of his on a case of intestinal disease was also exhibited.

Preparations and Appliances

A MODIFIED WATERS APPARATUS FOR THORACIC SURGERY

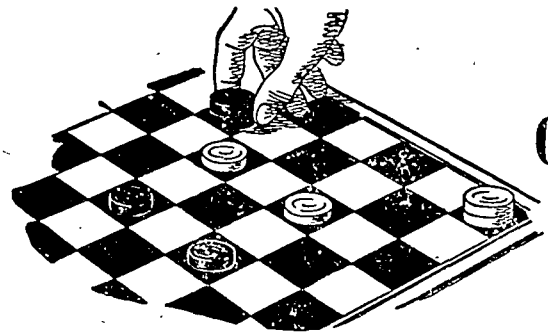
Dr. W. B. Bacon, visiting anaesthetist to the Royal Manchester Children's Hospital, St. Mary's Hospital, and Christie Hospital, writes: One of the difficulties with a Waters canister is the secure anchorage of the heavy soda-lime container. This is overcome by a simple clamp, fitting any operating table, to which a slotted length of steel about 14 in. (35 cm.) long is secured by means of a wing nut. This steel arm at its distal end carries a ball-and-socket joint which holds the canister and bag. The arm slides on the table clamp to any desired position, and the ball joint can be locked in any position suitable for holding the canister. Instead of the usual rubber bag the

WHERE OTHERS FAIL . . .

Aureomycin Hydrochloride

AUREOMYCIN HYDROCHLORIDE *Lederle* gives promise of being one of the most versatile antibiotics yet discovered. It is a potent antibiotic against many Gram-negative and Gram-positive organisms and against primary atypical pneumonia. AUREOMYCIN has been found useful in the control of infections caused by penicillin-resistant Gram-positive cocci (especially staphylococci), and infections caused by coli-ærogenes bacteria. It is also highly specific against rickettsial infections. AUREOMYCIN has been used successfully against infections that have become resistant to penicillin, streptomycin, or sulphonamides, and in patients who exhibit severe and uncontrollable sensitivity to these latter drugs.

ADVANTAGES



Aureomycin exhibits the following advantages :—Essentially non-toxic (excepting allergy) . . . Unlikely to produce fastness in pathogenic organisms . . . Effective against many organisms previously insusceptible to chemo-therapy . . . Available in oral . . . and topical ophthalmic dosage forms.

CAPSULES: Vials of 16 capsules each containing 250 mg.
OPHTHALMIC: Vials of 25 mg. with dropper assembly; solution prepared by adding 5 cc. of distilled water.

GAINING TWO AND LOSING ONE

Gaining two and losing one may be good draughts, but it usually is not sound therapy in peptic ulcer. Yet that is what may occur when ordinary alumina gel reacts with gastric HCl to form astringent chloride. Efforts to relieve the resulting constipation may partially offset the healing effects of alumina therapy.

Gelusil* Antacid Adsorbent tablets provide a specially prepared alumina gel which remains virtually unaltered in contact with hydrochloric acid in the stomach. Gelusil forms a protective colloid which permits normal healing without producing constipation, acid rebound or alkalosis.

Each tablet—Mag. Trisil. 7½ grs.
Alum. Hydrox: gel 4 grs.

Why Ribena in Wounds and Fractures?

Because hypovitaminosis-C inhibits formation of reticulum and collagen, thus retarding healing and adversely affecting the condition of the resulting scar. Similarly it interferes with normal callus formation. Because, too, 'Ribena' is a particularly rich source of the natural vitamin-C complex. 'Ribena' consists solely of the undiluted juice of fresh ripe blackcurrants and sugar; it provides a minimum of 20 mgm. of vitamin-C per fluid ounce.

Many surgeons employ 'Ribena' both pre- and post-operatively, particularly in operations on the gastro-intestinal tract and in orthopædic procedures. Important indications also are cases on acute and chronic sepsis, such as contaminated wounds and infected sinuses. More detailed information will be gladly sent on request.

Ribena is the pure undiluted juice of fresh ripe blackcurrants with sugar, in the form of a delicious syrup. Being freed from all cellular structure of the fruit, it will not upset the most delicate stomach. It is particularly rich in natural vitamin C (not less than 20 mgm. per fluid ounce) and associated factors.

Ribena (RIBES NIGRA) **BLACKCURRANT SYRUP**

The Successful Treatment of

FIBROSITIS

and certain cases of

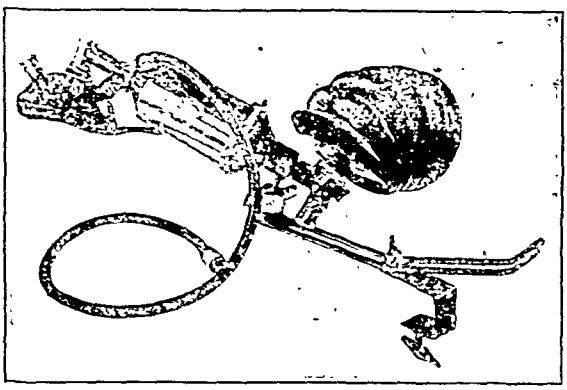
RHEUMATISM

with

NOVUTOX

A mass of evidence has accumulated to show that the treatment of Fibrositis and certain cases of Rheumatism with Novutox injections provides not only complete restoration of function with immediate relief from pain, but also, in many cases, early recovery.

Interested members of the medical profession are invited to write for a copy of a Thesis on "THE INJECTION TREATMENT OF FIBROSITIS—with special reference to: Lumbago, Muscular Rheumatism (Acute and Chronic); Muscular Pain (of Traumatic Origin)."



NOVUTOX is available in:
2-oz. and 20-oz. Bottles: ½%, 1% and 2% Solutions.
Boxes of 12 x 2 c.c. Ampoules: 1% and 2% Solutions.

Each c.c. of Novutox 2% contains 0.02 gm. ethocaine hcl., 0.00002 gm. epinephrine and 0.00002 gm. capryl hydrocupreinotoxin hcl. Other strengths of Novutox contain these elements (with or without epinephrine) in varying proportions.

PHARMACEUTICAL MANUFACTURING COMPANY
THE LABORATORIES, CHELTENHAM, GLOS.

Oxford vaporizer concertina type of bag is used, the capacity of which is 2.84 litres. There is an inspiratory valve and pressure gauge mounted on the bag fitting.

In addition to the usual expiratory valve on the Waters mounting an expiratory valve is fitted on the facepiece as near the rubber rim as possible, thus reducing as much as possible the dead space. Between the canister mount and the canister is an easily removable copper-gauze filter of the finest mesh. This is inserted in order to reduce the blow-over of soda-lime powder. It has not been found to increase breathing resistance to any appreciable extent. It is easy to remove the canister, readjust the holding mechanism, and use the apparatus for assisted breathing should this be required, as often happens during the

administration of curare. The photograph shows the apparatus with the soda-lime canister.

Leigh and Belton, in their recent book on paediatric anaesthesia, state that the soda-lime in the end of the canister nearest the facepiece is used up first, thus creating an additional dead space. They advise the use of a reversible canister. I use this apparatus at the Royal Manchester Children's Hospital for such procedures as Blalock's and Pott's operations for pulmonary stenosis. In these cases it is essential to have perfect control over respiration; the concertina type of bag, mounted near the child's head, materially helps this control. Cyclopropane is given, and it is my practice to use a Cobb's connector with the largest endotracheal tube (consistent with safety for the larynx), thus giving easy access for catheter aspiration. A facepiece, with gamgee pad, is employed instead of an endotracheal mount, as it is found that a better gas-tight joint is obtained, giving more efficient control of respiration, particularly when positive pressure is required for inflation of the lung.

All chest cases leave the theatre with the apparatus (without canister) attached; expiratory valves are fully open and a flow of not less than 6 litres per minute of oxygen is supplied from a cylinder attached to the bed. Not until the patient is safely transferred to the ward, and breathing is satisfactory, is the apparatus detached. Adults continue oxygen inhalation either by B.L.B. mask or by spectacle, according to their condition; children are housed in an oxygen tent.

I am indebted to Mr. Wardlaw, of the Christie Hospital, for the photograph, and to the British Oxygen Company for making the apparatus.

The British Rheumatic Association at its annual general meeting elected Colonel Stoddart-Scott, M.P., chairman. Air Vice-Marshal Don and Dr. Francis Bach were elected vice-chairmen for the coming year. Among the nearly one million disabled persons registered, only 35,000 are rheumatic sufferers, and these are mostly ex-Servicemen. The British Rheumatic Association is concerned to secure the privileges available under the Act for the large number of rheumatic sufferers who could benefit by it.

Correspondence

Tuberculosis: Certain Unexplained Mortality Figures

SIR,—Mr. G. Herdan (September 24, p. 706) has conveyed the impression, which is erroneous, that the ageing of the Scottish population is sufficient to explain most of the changes in the mortality from pulmonary tuberculosis in that country to which Mr. Walter Elliot (August 6, p. 297) had drawn attention.

In support of his contention Mr. Herdan has adduced a very roundabout argument, but, most strangely, he has failed to make a full examination of the available direct evidence—the mortality in specific age groups for each sex separately. These mortality rates are unaffected by changes in the age distribution of the population. I present them below; they show quite clearly that the changes in the mortality from pulmonary tuberculosis in Scotland, and in particular the divergence from the experience in England and Wales, cannot be dismissed as a statistical fiction.

TABLE I.—*Annual Civilian Deaths from Tuberculosis of the Respiratory System per 100,000 Civilian Population by Age and Sex in England and Wales and in Scotland, 1939 to 1947*

	Age Group				
	15–24	25–34	35–44	45–54	55–64
Males:					
England and Wales					
1939–41	67	93	97	120	124
1942–44	78	127	98	115	121
1945–47	56	80	75	104	118
Scotland					
1939–41	80	105	105	115	91
1942–44	97	127	105	109	98
1945–47	82	104	100	113	110
Females:					
England and Wales					
1939–41	85	75	49	35	31
1942–44	80	69	41	30	27
1945–47	72	69	40	27	24
Scotland					
1939–41	116	92	51	35	29
1942–44	143	99	52	28	27
1945–47	135	132	51	28	22

Table I presents the civilian mortality from the disease in England and Wales and in Scotland. To save space the death rates are given for triennial periods, but the annual figures also justify the comments which follow. Figures for Scotland in 1947 were kindly supplied to me by the General Registry Office in Edinburgh. Otherwise the information is taken from the published reports of the Registrars-General.

Males.—In England and Wales the mortality of civilian males aged 15–34 increased during the war and then dropped substantially in the period 1945–7. In the older age groups the death rate was fairly constant during the war period, and afterwards declined. The picture in Scotland for young adults was similar to that in England, but at older ages the rates increased slightly after the end of the war.

Females.—For civilian females in England and Wales the mortality in each age group declined during the period studied. In Scotland there was between 1939–41 and 1942–4 a definite increase in the death rate amongst those aged 15–34, the rates for the older women remaining steady. By 1945–7 the mortality had increased still further for the women aged 25–34; for the other age groups it remained at the 1942–4 level.

The civilian mortality rates from pulmonary tuberculosis were presumably inflated in both countries during the war years by selective recruitment of the more healthy individuals for military service. It may be assumed that the effect upon the death rates was very similar in the two countries, since the same conscription laws applied to both. Hence the ratio of the tuberculosis death rates in the two countries will be largely unaffected by selective recruitment. This comparison is presented in Table II, and it indicates the extent to which the Scottish experience has diverged both during and since the war from that in England.

TABLE II.—*Ratio of Civilian Mortality from Tuberculosis of the Respiratory System in Scotland to that in England and Wales, by Age and Sex, 1939 to 1947*

	Age Group				
	15–24	25–34	35–44	45–54	55–64
Males:					
1939–41	1·19	1·13	1·08	0·96	0·73
1942–44	1·24	1·00	1·07	0·95	0·81
1945–47	1·46	1·30	1·33	1·09	0·93
Females:					
1939–41	1·36	1·23	1·04	1·00	0·94
1942–44	1·79	1·43	1·27	0·93	1·00
1945–47	1·88	1·91	1·28	1·04	0·92

An example will make the interpretation of this table clear. The ratio of 1.19 for males aged 15–24 years in 1939–41 means that the pulmonary tuberculosis mortality among males of this age group was 19% above that in England. In 1942–4 the excess was 24%, and in 1945–7 it amounted to 46%. The other age groups indicate a similar (though lesser) deterioration of the Scottish experience in 1945–7 relative to that in England. Among females the divergence between the Scottish and English rates is particularly noticeable for those women aged 15–34. During the period 1945–7 the rates in Scotland were about 90% greater than those in England.

The statistical evidence thus indicates that: (1) the mortality from pulmonary tuberculosis among young adults in Scotland compares very unfavourably with that in England and Wales, and is relatively much worse now than it was early in the war; (2) the increase which has occurred since the war in the death rate from the disease amongst Scottish women aged 15–34 is a matter meriting the fullest investigation.—I am, etc.,

Oxford. IAN SUTHERLAND.

Modern Trends in Radiology

SIR,—The rather curious views propounded by Dr. James F. Brailsford (October 1, p. 724) as representing modern trends in radiology are not likely to be supported by his clinical and radiological colleagues. It is notable that in the bibliography all the references are to himself. He has always been an opponent of case finding as a method of control of tuberculosis, and states that "it can be proved to have been responsible for the infliction of much mental and physical pain." The following are the facts.

In this country three and a half million people volunteered for mass radiography. As a result of the initial examination 13,401 were found to be suffering from active tuberculosis necessitating treatment. Samples of these patients compared with samples of patients reporting with symptoms to chest clinics have shown that those detected by mass radiography require from six to seven months' treatment before returning to work, as against eighteen months to two years required by those reporting to chest clinics.

A still larger group of individuals with minimal tuberculous lesions or lesions of doubtful activity detected by mass radiography have been kept under observation while at work. Presumably it is in this group that Dr. Brailsford believes that we are inflicting physical and mental pain. Chest physicians following up these cases and contact cases do not report any adverse mental or physical effects on the individuals concerned. If Dr. Brailsford has facts and figures supporting his contention that these simple procedures are being so badly handled as to cause serious neuroses it is high time he produced them.

Dr. Brailsford, in similar vein, makes a surprising criticism of Professor Morgan's work on the early diagnosis of carcinoma of the stomach, and suggests that he abandons it until "a cure for malignant disease is discovered." It is not misinterpreting Dr. Brailsford to summarize his views on the diagnosis of tuberculosis and carcinoma as follows—wait until the patient has a big haemoptysis or a palpable tumour.

Time prevents me from commenting on many other statements in this article which cannot be substantiated by facts. Its general tenor can be judged by such remarks as, "Mass surveys are essentially bureaucratic regimental measures, designed by officials and enthusiasts." And again, injection of opaque media "can, in the long run, result in atrocities, cruelties, or licensed murder." It is deplorable that such nonsense should have been given space in a scientific journal.—I am, etc.,

London, W.1. PETER KERLEY.

SIR,—Dr. J. F. Brailsford (October 1, p. 724) is again severely critical on the subject of mass radiography. Let us analyse some of his objections for what they are worth.

First he says, "Mass surveys are essentially bureaucratic regimentation." As far as chest radiography is concerned nothing could be further from the truth. The whole procedure is entirely voluntary from the first miniature film taken to the final clinical examination in abnormal cases. The fact that a number of people are able to pass through the unit in a short space of time smacks no more of bureaucracy than does the walking through the turnstiles of the Motor Show.

Secondly he says, "Mass radiography has added nothing new to our knowledge of radiography of the chest." Here again I would dispute his words very strongly. Quite apart from pulmonary tuberculosis, what about the unsuspected early *neoplasms* which are discovered? Up to the end of 1947 257 cases of pulmonary *neoplasm* were picked up by units in this country, 198 of which are known to have been referred to thoracic surgical units (Ministry of Health figures).

Apart from Dr. Brailsford, I think that practically every physician in the country recognizes and applauds the early detection of pulmonary tuberculosis by miniature radiography or any other means. Every experienced worker in the field of tuberculosis knows that some lesions, even if they appear soft radiologically, do not progress over a period of years, whereas others will spread rapidly. What nobody can yet say is exactly which type of lesion will or will not heal. Our knowledge in this field can only be broadened by the serial observation of more and more of these unsuspected cases.

The "stigma of being labelled tuberculous," which Dr. Brailsford so greatly fears, is surely diminishing in this enlightened age and will continue to do so if we find and boldly follow up all types of case.—I am, etc.,

Keresley, near Coventry. A. GORDON EVANS.

SIR,—No one could doubt the truth of Dr. James F. Brailsford's statement (October 1, p. 724) that there would be fewer errors in the interpretation of radiographs if radiology was always preceded by a sound clinical examination, but the second part of his statement, as far as diseases of the chest are concerned, is simply untrue and quite unsupported by experience.

I do not know how many chests Dr. Brailsford examines clinically, but I can put my experience on record. Of the 31 cases of pulmonary tuberculosis now awaiting admission for sanatorium treatment from my area, only 10 patients had signs which were revealed by clinical examination by, at least, two different examiners. One of the 10 patients has a large pleural effusion, five have far advanced, extensive, and incurable lesions, and only four have some chance of recovery by adequate treatment. Had, in the other 21 cases, radiography been omitted in favour of a negative clinical examination the consequences would have been disastrous.

It is highly regrettable that at the time when in medical papers all responsible workers who know every aspect of tuberculosis incessantly try to impress on the general practitioners the absolute necessity of referring all suspicious cases for a radiological examination as early as possible, notwithstanding whether clinical examination reveals any signs, unqualified views should be expressed with apparent authority to the effect that "the least harm will come from omission of the radiograph and most from omission of the clinical examination." Such a statement, without any evidence to support it and quite contrary to the experience of all chest physicians, can only achieve one purpose, to confuse the general practitioners, who to a great extent rely on the reading of scientific papers, and to diminish the co-operation with chest physicians with the result of losing valuable time and lives.

As regards Dr. Brailsford's remarks on mass radiography, is it possible that Dr. Brailsford has in the heat of the argument momentarily forgotten that tuberculosis is an infectious disease? I recently experienced some difficulty in persuading a young bus driver who "never lost a day's work" to be examined at the clinic after his 14-months-old baby had died of miliary tuberculosis. Actually his views, probably obtained from the lay press, were very much like those expressed by Dr. Brailsford, but at last he gave in and his *x*-ray film showed a large cavity in the left apex and his sputum was positive. Does Dr. Brailsford really think that in this case, and in similar cases which are a commonplace experience in any chest clinic, that a mass radiography survey, which would have picked up this man before fatally infecting his child, would have only "seriously interfered with his life without contributing any good"?

Every sane person will agree with Dr. Brailsford that "there would appear to be no more justification for removing a healed or quiescent lesion of the lung (which would not have been suspected if there had been no radiograph) than of any other structure, or in fact for removing any normal tissue; since valuable healthy lung is removed." But this sentence, read together with the previous paragraph stating that "the most successful surgical results have been obtained in cases which have previously healed themselves and are symptomless," implies that thoracic surgeons quite unnecessarily perform mutilating operations on patients with healed lesions. I doubt very much whether Dr. Brailsford really realizes the seriousness of this charge. A surgeon who would perform a major and often mutilating operation unnecessarily would be guilty not only of gross ignorance but at the same time he would expose himself technically to a legal suit by the patient for causing grievous bodily harm. It is not certain to me whether Dr. Brailsford levelled this very serious charge against American surgeons based upon his American experiences or whether he left in his American audience the impression that this sort of thing is being done by British thoracic surgeons, but the fact is that the reputation of British medicine and surgery is still very high in the United States and such a serious accusation should not pass unchallenged. As these utterances were made not only in print but apparently in several lectures in the United States, Dr. Brailsford should either substantiate this statement by incontrovertible evidence or should withdraw it publicly without reservation.—I am, etc.,

F. Kellerman.

Colchester, Essex.

Essential Hypertension in Pregnancy

Sir,—I feel it my duty publicly to acknowledge how deeply I deplore the fact that I have misunderstood Mr. R. H. Paramore's ideas on the mechanism which induces hypertension and causes renal cortical ischaemia in pregnancy. I might possibly be excused on account of the way in which Mr. Paramore expressed his ideas in his letter in the *Journal* of August 27 (p. 486). I quote from this letter: "In my view spinal analgesia acts by inducing a state comparable with shock. There is a great fall of blood pressure, and blood is not thrust into the renal medulla to maintain the obstruction to the exit of urine from the uriniferous tubules." To me it seems logical that if the belief of Mr. Paramore was that the spinal analgesia helped by preventing the blood from being thrust into the renal medulla it was because he thought this to be the responsible factor. However, as no one could know Mr. Paramore's ideas on the subject better than himself I am really admitting my mistake and again plead to be pardoned for my apparent lack of clairvoyance.

One thing I can state without hesitation—namely, that my letter (September 17, p. 650) answering Mr. Paramore's direct reference to me and to the book in the writing of which I collaborated was not dictated under any "misapprehension"; on the contrary, it was written with all sympathy to Mr. Paramore for his pioneer contribution to the treatment of eclamptic patients by means of spinal analgesia.—I am, etc.,

J. Trueta.

Oxford.

A New Neonatal Syndrome

Sir,—In reference to the letter by Drs. Crystal Bates and A. P. M. Page (October 1, p. 756) adding another case to the interesting series published by Mr. W. G. Mills (August 27, p. 464), we should like to record that we have seen 20 similar cases in Liverpool, the details of which we intend to publish shortly. We believe these cases were due to the intra-arterial injection of "cycliton," but we have not seen similar effects follow the use of lobeline.—We are, etc.,

F. P. Hudson.
Anne McCandless.

Liverpool.

Penicillin in Early Syphilis

Sir,—Your annotation on this subject (September 24, p. 694) presented in able fashion the position at this moment of transition, but I should like to take exception to the statement that the results of Eames and Miller (p. 672) "are appreciably worse than those reported *after similar treatment* [my italics] by McElligott, Jefferiss, and Willcox." Surely, Sir, the secret of the better results obtained by the latter method[1] lies in the choice of a more effective arsenic and bismuth course rather than in the method of employing penicillin, since it is generally accepted that the method using a daily single shot of penicillin in oil-beeswax is not superior to the three-hourly regime of adequate penicillin dosage in aqueous solution. The essential basis of this course consists in the concurrent administration of arsenic and bismuth twice weekly over a period of six weeks,[2 3] and the Ministry of Health recognized its value in preventing clinical and serological relapse in 1943.[4]—I am, etc.,

O. A. F. Ross.

Liverpool.

Myxoedematous Madness

Sir,—Dr. R. Asher's article on myxoedematous madness (*September 10, p. 555*) gave prominence to hypothyroidism as the aetiological factor in certain psychoses. The exhibition of thyroid extract in psychoses has frequently been tried with disappointing results, except in some cases of schizophrenia, and apart from myxoedema the mechanism of the therapy is very obscure. Hyperthyroidism is classified as a psychosomatic illness, and a considerable proportion of cases are an expression of an anxiety state. Occasionally it is associated with a manic-depressive psychosis. Because of this rare association of thyroid dyscrasia and psychosis I feel the following case is worthy of quotation.

A married woman, aged 49, came to see me in March, 1948. She was depressed and sleepless at nights. She felt "awful" in the mornings and found everything too much trouble. There was no evidence of physical disease, and I decided she was a case of mild involutional depression. She responded well to dextro-amphetamine sulphate and a sedative at night; but when after a year of this treatment she was much the same and very dependent on drugs I decided it was time she saw a psychiatrist. He agreed with my diagnosis and advised E.C.T., but she could not face the idea of a mental hospital.

In April, 1949, she became profoundly depressed. She felt so wretched she said she would agree to any treatment and went as a voluntary patient to a mental hospital. She stayed there for five days and then returned home as bad as ever. I was loath to certify her, and while I was observing her the picture changed completely and dramatically: within a month she was the picture of thyrotoxicosis. She lost weight, sweated profusely, had a tachycardia, and her thyroid gland enlarged. She looked a textbook picture. With the advent of this new syndrome her depression vanished. She became cheerful and started eating and sleeping. Thyrotoxicosis was confirmed at the local hospital, and she was put on the waiting-list for operation. Her admission was delayed until July, 1949, during which time she became manic. She arose at 4 a.m. and cleaned her house from top to bottom. She could not keep still—this with a pulse of 140 and oedema of her ankles. These symptoms subsided

on thiouracil, and when she was finally admitted for operation there was no marked psychic abnormality. Her thyroidectomy was uneventful, and she is now her normal self. She is still a bit apprehensive about exerting herself and doing a full day's work, but she eats well and sleeps well and keeps cheerful without any marked swing of affect.

In this case thyroid auto-intoxication appeared to raise endogenous depression. Mania intervened but was controlled by thiouracil. Thyroidectomy appears to have cleared the condition except for some residual anxiety such as one would expect after such a long illness. Was this a series of coincidences, or was there cause and effect? As in Dr. Asher's cases thyroid alleviated the condition, but she was no case of myxoedema in the first instance.—I am, etc.,

Ibstock, Leics. C. A. H. Watts.

Sir,—I feel confident that Dr. E. B. Davies has indeed earned the gratitude of all physicians and psychiatrists with his interesting letter (September 24, p. 706) on myxoedematous madness. When we next encounter a case of myxoedema with psychosis we must earnestly remind ourselves that the association of these two relatively rare disorders is probably fortuitous. Moreover, should the mental symptoms disappear as the myxoedema responds to thyroid we must remember that this, also, is likely to be accidental. After all, psychoses do remit or subside spontaneously.

On the other hand, if we have helped a psychotic patient to recall with emotion some highly significant event, such as, for example, having seen in childhood his mother or her father in the bath, we may rejoice at having struck gold. For then we can be quite certain that we have skilfully unearthed the specific cause of the mental disease, and not merely some irrelevant association.—I am, etc.,

Dumfries. Martin Roth.

Old Age

Sir,—I fear the wording of one or two phrases in my letter on old age (October 1, p. 758) was unfortunate. Naturally I was speaking to my colleagues, and all doctors know that euthanasia is not allowed. In any case, I no longer believe in it, as I am a Catholic. The mention of it was meant to be more in the nature of a query to other doctors—especially non-Catholics—as I am anxious to know their point of view about selfish and apparently useless old people.

But there are other, and kinder, and easier ways, surely, of dealing with such cases. One I mentioned was segregation—and here I would advocate the formation of another society—there is room for one—a society governed by a panel of a few doctors, clergy, and one or two barristers. Let this panel have authority to deal with the cases of hardship and frustration mentioned. Cases could be reported to the panel, or the down-trodden victims could consult it. Further, this panel should have authority to order segregation or other treatment. There are plenty of big, roomy rectories which the occupiers would be only too glad to vacate.—I am, etc.,

Portsmouth J. Rushworth Lund.

Sir,—I hope you will take up Dr. Lund's challenge (October 1, p. 758). Must we for ever, as a profession, pass by on the other side? Over 75, we become increasingly conscious that we are cumberers, but how can we combine effectively to express that point of view and get the co-operative help of those who bear the burden and heat of the day?

The last twenty-five years have shown how public opinion can change in such a matter as a general acceptance of cremation, for example. Must voluntary euthanasia be for ever "impossible" for serious discussion without such a prefix as "brutal" being applied to it?—I am, etc.,

"Seventy-nine."

Sir,—A letter by Dr. J. Rushworth Lund appeared in the *Journal* of October 1 (p. 758) entitled "Old Age." Many like myself must have read it and no doubt asked themselves the same questions that occurred to me. (*a*) Is the letter intended as a joke? (a poor one admittedly). (*b*) Is it merely a flippant response to the spate of enthusiastic articles on geriatrics? (*c*) Is it a bait to stimulate correspondence on the many problems concerning old age which are on the *tapis* at the moment as a result of recent legislation on health and welfare? (*d*) Could it, by any possibility, be meant to be taken seriously? I confess I do not know the answers to these questions.

It is, however, well that we should accustom ourselves to the idea that we are an ageing population, that the proportion of elderly persons to the wage earners has greatly increased. All the implications of this are by no means fully recognized. We need not, however, disturb our minds with erroneous ideas as to the selfishness of the old or that "so many live only for themselves," for we know better. Selfishness is inherent in all of us. From the moment we are born we are selfish. If we are spoilt in childhood and not trained to resist such impulses the fault grows in us, and if in adult life the spoiling goes on, as sometimes happens, then probably it will last into old age. For this we must not blame the old but rather pity them. Such persons are rarely happy, and who are we to sit in judgment on the faults of our neighbours? Some, it is true, may be a thorn in the flesh of those to whose lot it falls to look after them, but thorns are an essential part of life.

As to the question, "Why encumber they the ground?"—the only answer is yet another question, "Why encumber *we* the ground?" To question one corner of the plan of life is to question it all.

As to euthanasia, it is only when one reads a letter of this type (and maybe it was after all only a joke) that the hideous possibilities of such procedures suggest themselves to one's mind.—I am, etc.,

E. M. Hickey.

*** Several other correspondents have written to express their disagreement with Dr. Lund's earlier letter. This correspondence is now closed.—Ed., *B.M.J.*

B.M.A. Tuberculosis Group

Sir,—With the setting up of the Tuberculosis Group of the B.M.A. there are a number of urgent matters needing consideration. For many years the profession has played with the problem of the prevention of human tuberculosis of bovine origin. Dr. J. Arthur Myers[1] has claimed, "The control of tuberculosis in cattle, therefore, has markedly reduced the incidence of tuberculosis infection, the morbidity, and the mortality from tuberculosis in man." To-day only 16% of our cattle herds are certified free from tuberculosis. It is time that pressure was put on the Government to complete this eradication of bovine tuberculosis within a fixed date.

The next question that requires careful consideration is that a proper critical examination should be made and published of the results of treatment in all public sanatoria. Radical changes in our present methods for controlling this disease may be found necessary. The association of cancer of the lungs with tuberculosis in the lungs or in some other organ of the body is also worth investigating.—I am, etc.,

Itchingfield, Sussex. Sydney Gordon Tippett.

Men, Machines, and Materialism

Sir,—Inevitably there arise in the tides of men's affairs issues which demand attention. Wars and their accompanying problems call for direct action, and commonly the men and the means are found and the resources of the people are urgently deployed. There follows almost inevitably a period of relative exhaustion and uncertainty. With these phenomena we are familiar. With the threat of physical extinction or subjection we have grappled not once but again, and with a remarkable unanimity and singleness of purpose. To minimize the eroding effect on a civilization of two major wars in one generation would be futile, but the contemplation of certain human trends—trends which display the "inevitability of gradualness" and a malignant persistence—cannot fail to be gravely disturbing.

Two recent publications in your own columns have met and faced the most disquieting of these problems.

Professor Geoffrey Jefferson, in his Lister Oration (June 25, p. 1105), has assessed the value of the concepts embodied in Dr. Norbert Wiener's book *Cybernetics* and appraised the use of the varied analogies there propounded; but he sees "danger threatening—that of anthropomorphizing the machine," and ends by ranging himself with the humanists. Dr. F. M. R. Walshe, in his letter (August 13, p. 383) inveighing against the most recent example of "materialism" within our own gates, sees us being led "from the free status of a learned profession to that of a sub-group of that drab and alien abstraction 'economic man.'"

Not the least of our perils lies in our own approach to this spreading cult of materialism. Scientific method induces us to weigh and to analyse evidence and motive, and there is a compelling charm in these procedures which may blind us to the fact of our essential humanity and to the existence of the "incommunicables" which go to make it. Study of the computing machine and allied mechanisms may help us to greater understanding of those cerebral mechanisms which are explainable in such terms, and "analysis" (in the psycho-analytic sense) has afforded and may continue to afford us greater insight into the motivation of human behaviour. But the "analytic situation" and the "mechanistic analogy" may assume disproportionate significance, and paralysis of action with spiritual sterility ensue.

Other disciplines than ours stand thus imperilled. Professor F. H. Ayers (*Reflections on Our Age*) has shown how philosophy has long concerned itself with the minutiae of human conduct and endeavour but finds that though the "aims of philosophy" may be to discern how men ought to live there is as yet no common agreement how they should. So may the web become denser, the skein more tangled, and thus persist "the always frustrated struggle of human contrivance relying on itself" (Charles Morgan, *The River Line*).

There, Sir, I submit, lies the challenge to-day. The liberal profession of medicine no less than any other can refuse this challenge, can acknowledge the advance of materialism, can go with the tide. It may be argued that this conflict has progressed too far. I would remind you that the epic actions have always been fought by the rearguard, as at Roncevaux and at Thermopylae. To refuse the challenge is not to court defeat; it is to accept it.—I am, etc.,

Taunton, Somerset. R. SESSIONS HODGE.

St. Luke's Day

SIR,—The eighteenth of October is St. Luke's Day. On that day Christians in all parts of the world commemorate the patron saint of the healing profession. They recall with gratitude the gospel that he wrote for his fellow men. On that day the Church recalls with thankfulness the fact that this physician was called to be "an evangelist and physician of the soul," and prays that "by the wholesome medicine of the doctrine delivered by him, all the diseases of our souls may be healed." That is indeed a consummation devoutly to be wished. Let us study these prescriptions for the soul of a world, sick nearly to death, which this physician had learned from the Master and has preserved for us. In these latter days modern scholarship, and modern translations of Luke's Greek manuscript, give us the opportunity of understanding better perhaps than preceding centuries these prescriptions for a new way of life and health for a sick world. Was Renan right in calling this small book of this Gentile doctor "the most beautiful book we possess . . . a book full of joy"?

It is a pen portrait by a literary artist of the human Jesus Christ: of a man fond of little children; the champion of the cause of women; the Rabbi who welcomed women as his disciples; the friend of hated Quislings and notorious sinners shunned and neglected by the orthodox of his day; the Teacher who could remake these wrecks of humanity, transforming Quislings into true patriots and great sinners into saints, converting Matthew the tax collector to Matthew the scribe of the Kingdom, and Mary of Magdala to be Mary Magdalene, first witness of his resurrection to his chief apostles. This joyful book of Luke's is full of the joy of lives that seemed failures, hopeless failures, transformed to be happy and successful beyond all belief. And this miracle was effected by love—forgiving, understanding love, such as the world had never witnessed. Luke's own closest friend and colleague in his later life was perhaps the greatest case of this incredible marvel—Saul of Tarsus, the arch-persecutor of the early Christian church, the narrow nationalist Pharisee, transformed into Paul the devoted missionary of Christ to the Gentile world. And Luke's second great book, *Acts of Apostles*, is devoted to recording the work of Peter and Paul, both of them failures—transformed, both of them, by the resurrection of Christ, to become His messengers-in-chief to the world—both of them dying, if the tradition be true, as martyrs for "the gospel" at Rome.

Can the present sickness of the world's soul be remedied, or is it past redemption? It is the message of St. Luke (and St. Paul) that it can be remedied—that the world's sick soul can be cured. But only by the medicine prescribed by the Master Physician as recorded by St. Luke and his colleague St. Paul, in the gospel and *Acts of Apostles*. And the "active principle" of this "medicine" is derived from the historic fact of the resurrection of Jesus. That is the astounding climax to which Luke's first "treatise" leads, making sense of Jesus' mission and message to the world. Surely our mammon-ridden, war-weary world to-day needs the "wholesome medicines" prescribed in the *Gospel of St. Luke* and *Acts*: "You cannot serve God and Mammon," and "Remember the words of the Lord Jesus when He said, 'It is happier, more blessed, to be giving than getting.'"—I am, etc.,

Banstead, Surrey. HERBERT CAIGER.

Sensitivity to Streptomycin

SIR,—Dr. M. C. Wilkinson (September 24, p. 707) sets out some of the problems associated with the development of streptomycin sensitivity in nurses. He adds that by reporting experiences some way of protecting persons sensitive to streptomycin may be found. I therefore briefly report a case of streptomycin sensitivity to illustrate some other aspects of the problem which this condition presents.

Eleven months after commencing handling and administering streptomycin, a nurse, aged 43, with menopausal symptoms and of neurotic disposition, developed puffiness and itching of the eyelids. This was thought to be due to a local condition, but no local cause was found. Four weeks later the realization that the condition might be due to streptomycin sensitivity led to the carrying out of a patch test. This gave a strongly positive reaction. The chemosis of the eyelids increased and she felt unwell. She was at once removed from work involving the handling of streptomycin, she was given "anthisan" by mouth, and the condition cleared up within a week.

Four months later the swelling of the eyelids recurred, and in addition there was flexural dermatitis of both elbows. Interrogation revealed that she had recently been handling soiled linen which included napkins belonging to children receiving streptomycin for tuberculous meningitis. Once again the condition was controlled by removal from the apparent source of contact and by the administration of anthisan by mouth. Three months later a dermatitis appeared *on the wrists and hands as well as the other areas previously involved.* A month later, two days after commencing the use of a simple ammoniated ichthyol ointment to the eyelids, a severe chemosis of the lids occurred which subsided on stopping the use of the ointment. The dermatitis remained quiescent for a period of two months until recent weeks. Now, ten months after the first manifestation, a widespread contact dermatitis involving the forehead, neck, eyelids, elbows, wrists, and hands has occurred necessitating her being put off duty. Anthisan is now ineffective.

This case illustrates several points. As in Dr. Wilkinson's first case, the original manifestation of the sensitivity was in the eyelids and not on the hands as would be reasonably expected. In the second place, protection by wearing rubber gloves whilst handling streptomycin solutions may give a false sense of security if no protective measures are employed when other sources of contact such as soiled linen are handled. Most important of all, when sensitivity develops it is a very distressing and incapacitating condition which appears to persist after all obvious sources of contact with streptomycin have been excluded. This raises the question as to whether development of streptomycin sensitivity predisposes to sensitivity to other

accents. The fact that the development of streptomycin sensitivity in a nurse may accentuate the already critical shortage of tuberculosis nurses is a side-issue of no little importance.

I wish to acknowledge the help given by Dr. R. Aitken, Dr. G. A. G. Peterkin, and Dr. J. Macaskill in this case.

I am, etc.,

Edinburgh. N. W. HORNE.

Massage with Adrenaline

SIR,—My attention has been drawn to a letter by Dr. G. L. Foss on this subject (October 8, p. 816). I wish to point out that the circular to which he refers has no connexion with my article (*Medical World*, April 15, 1949). In it no suggestion was made of any relation between the adrenaline-cream treatment for chronic rheumatism and Kendall's "compound E," and the treatment of rheumatoid arthritis was not even mentioned. I wish especially to disclaim any association with, or knowledge of, the pamphlet to which Dr. Foss refers.—I am, etc.,

London, W.1. LOUIS MOSS.

Simulated Amnesia

SIR,—May I point out to Dr. Harold Palmer (August 27, p. 487) that I have put forward and fully discussed the contention that malingering only occurs in the hysterical personality (*Psychiatry, A Short Treatise*, 1948, Bristol, pp. 109 and 115)? This would appear to agree on all major points with his remarks in his letter. Malingering as a psychiatric notion should be discarded, as it carries a definite legal implication. From the medico-legal point of view it is unlikely that a diagnosis of hysteria would in any way distort the judgment of the courts in favour of an evildoer. Society cannot be expected to pay for the behaviouristic experiments of the so-called malingerer, of the hysteric, or of the psychopathic personality. By discarding the term "malingerer" no harm would therefore be done, while the integrity of psychiatric nomenclature would be preserved.—I am, etc.,

Kingswinford, Staffs. W. A. O'CONNOR.

Hypnosis in Treatment

SIR,—I am glad that my letter (September 17, p. 653) has stimulated some interesting views on hypnosis. However, I remain far from being reassured about its possible dangers.

Dr. Neville Murray (October 1, p. 756) admits that my postulates are correct in part, while the other parts of the whole remain among the great unknown imponderables. He mentions the Rorschach test as being one which gives objective evidence of personality structure. Although I have no experience of it, I believe that it works on the principle of the ink-blot test, and I would be surprised to find it more than a rough measure, which is difficult to assess and judge, apart from the preconceived ideas of the widely differing schools of psychology or from the subjective personality of the examiner. While some aspects of personality are rightly the concern of psychology, we cannot concede that other scientific and human disciplines should not be entitled to an equal or greater concern. Lastly, he makes an inaccurate presumption as to conceptions I am supposed to hold—I used the word "influence"; he uses the term "mental assault."

Dr. A. P. Magonet (p. 756) also makes an inaccurate presumption in stating that I believed hypnotized subjects to be "passive automatons." Fortunately there are limits to what even they will accept in the way of suggestion; we all know that well enough. He cites the case of a girl with cardiospasm who could not swallow the fact that her mother had died. This presupposes that the girl was intellectually capable of conceiving a symbolic idea containing a high degree of abstraction.

Symbols of this kind are all very well for the highly educated, but symbols in general are originally spontaneous and relevant, unless the subject is very suggestible and the idea is implanted from outside, which may well have been the case in this patient. Death is associated with ritual eating admittedly—e.g., wakes and the now extinct sin-eater—and we know something about the history of such practices. They are considered to be inappropriate to modern thought, but may be the basis of this symbol. The fact is that two separate events occurred at the same time with all probability of causal connexion. The nexus might consist of a symbol but might also be of a different nature altogether—e.g., a chronic manifestation of the swallowing difficulties some of us have felt in acute form while awaiting viva voce examinations. In this case feelings of emotional insecurity at the mother's death would give rise to the state of chronic anxiety, only understood in part by the patient, whose attention is concentrated on the symptom.

Under hypnotism, with the critical faculties depressed voluntarily even if not altogether in abeyance, it is likely that a variety of more or less plausible explanations would be acceptable. If the explanation is accepted by the patient in a case of that sort the symptom may disappear. So it has always done over the face of the globe and for many centuries.

Such examples do nothing to alter my conviction that the more widespread use of hypnotic methods for symptoms arising in patients not generally considered to be hysterical brings possibilities of dangers to the personality not at present realized. The fundamental criticism of hypnosis is an urgent need and must come from abler people than myself, as I have already suggested. Until more is known of its nature and long-term effects its use should be limited.—I am, etc.,

Birmingham. K. M. HAY.

Treatment of Early Pulmonary Tuberculosis

SIR,—The position regarding the treatment of early pulmonary tuberculosis is still deplorable. In my area it is usual for a patient to be told that he may have to wait for six months or more before being admitted to a sanatorium, even though he be a young person with an early lesion. Domiciliary treatment is handicapped by the fact that there are too few tuberculosis medical officers to help with the work.

If general hospitals were asked to deal with a sufficient number of these patients to reduce the sanatorium waiting-lists to a few weeks they would find that their own waiting-lists for other patients would be impossibly long.

I suggest that the B.M.A. approach the Minister of Health with the object of finding ways and means of providing more beds for the treatment of these cases. This would mean opening hospitals now closed for one reason or another, building others, and attracting staff to them by means, perhaps, of higher pay. This should have priority in the N.H.S., even if this means greater economy in some other parts of the Service.—I am, etc.,

Dorchester, Dorset. J. HERBERT-BURNS.

Manipulation for Low Backache

SIR,—Dr. N. B. Eastwood's letter on manipulation for rheumatism (September 24, p. 710) will probably stir many doctors to action, either mentally to contradict or manually to try their hand. Dr. Eastwood must be congratulated on manipulating his cases of low backache, for this takes considerable time in a busy practice. That it is the correct thing to do I am in no way in doubt, especially as soon as possible after it is first reported. That at least three-quarters of his patients benefited considerably is very satisfactory.

Two of his statements, however, invite criticism. The title of his letter continues to breed confusion of thought. The low backache and not rheumatism is the complaint and reason for manipulating. It is this pain in the back or buttock or the constant ache that the patient complains of. The doctor should not call it rheumatism or fibrositis. That the diagnosis is "probably of articular origin" is not in doubt by those who manipulate, but to state that the manipulation "appears to act on the sacro-iliac joint" is quite incorrect. The cause of low backache has been conclusively shown by many authors to be due to derangement of a lumbar intervertebral joint in the majority of cases. The sacro-iliac joint can easily be tested and excluded as a cause.[1]

The manipulation described is interesting but complicated. It can more easily be performed on a couch in comfort, with two or three variations should improvement not take place.[1]

The principle of the manipulation described is probably quite incorrect. The essential points are that some flexion of the lumbar spine and rotation at the same time be maintained and augmented momentarily by excessive rotation. The partial flexion is essential in that the posterior aspect of the intervertebral joint is widened, so as to allow the nucleus pulposus to return to its correct place. When extension is attempted on these cases it frequently temporarily aggravates the condition.

Before manipulation is attempted in cases of low backache it is hoped that the patient is carefully examined systematically, testing all spinal movements, sacro-iliac joints, hip-joints, and muscle strength of both legs, not forgetting the abdomen and a rectal or P.V. examination. Otherwise indiscriminate manipulating for low backache will be disappointing and patients will not grow to trust the doctor who manipulates. With experience and practice it is a most essential accessory to one's armamentarium.

In my experience manipulation is the only preliminary treatment of any value in a deranged lumbar intervertebral joint in the right type of case. Manipulation should always be followed up by extension exercises of the trunk. In those cases in which recurrence is frequent epidural injection or a lumbar corset may help.—I am, etc.,

Locked Twins

SIR,—The purpose of this letter is to place on record a patient who had locked twins at Rosedene Maternity Hospital, Inverness, in March, 1949.

The patient, a 19-year-old primigravida, had been under observation in hospital for six weeks prior to delivery because of pre-eclamptic toxaemia. Pre-natal *x*-ray examination showed twins, one of which lay as a vertex and the other as a breech presentation. Labour started spontaneously at the 37th week and followed a normal course. The first infant, a breech presentation, delivered spontaneously to the neck from the left sacro-anterior position. Vaginal examination now revealed that the head of the second foetus was well down in the pelvic cavity in the left occipito-posterior position with the head of the first still at the pelvic brim. Attempts to disengage the infants were unsuccessful, and by the time specialist aid could be summoned the first infant had succumbed, so it was decapitated and, the second bag of membranes having been ruptured, the second baby was gently extracted with the forceps. The head of the decapitated infant was then delivered by passing the middle finger into its mouth, the other fingers protecting the uterus from damage by the severed vertebral column. The extraction was accomplished by traction and suprapubic pressure. After a normal third stage, inspection of the placenta proved it to be of the uniovular type. The infants were both males weighing respectively 4 lb. (1.81 kg.) and 4 lb. 1½ oz. (1.85 kg.).

—I am, etc.,

Inverness. JAMES W. DAVIDSON.

Treatment of Cutaneous Anthrax

SIR,—The description of the diagnosis and treatment of cutaneous anthrax by Drs. John A. Holgate and Reginald A. Holman (September 10, p. 575) should not pass without comment. Northampton, a centre of the leather industry, has a fairly steady incidence of cutaneous anthrax, and I have been responsible for the diagnosis and have followed the treatment of some 20 cases during the last eight years.

On admission the patient is given 0.45 g. of "stabilarsan" and 100 ml. of serum subcutaneously. A second 100 ml. of serum is given later if the clinical condition of the lesion warrants it. With this treatment recovery has always been uneventful. Two cases, however, were treated with penicillin. Both developed a sharp rise of temperature shortly after the injection, and there was a great increase in inflammatory reaction around the lesion. The condition of the patients deteriorated, and it was considered necessary to administer amounts of serum greatly in excess of those normally used. The penicillin appeared to be responsible for the unusual severity of these cases and its use has since been abandoned.

I would suggest that penicillin causes a sudden destruction of a large number of anthrax bacilli, with a liberation of endotoxin which increases the local inflammation and causes pyrexia. The literature on the treatment of anthrax by penicillin suggests that the disease is of great severity and danger, and that vast doses of penicillin are needed to control it. In our experience cutaneous anthrax is not a severe disease and is easily controlled by the use of serum and stabilarsan. Intravenous injection of the serum is rarely necessary or desirable. May I suggest that in their next series of cases Drs. Holgate and Holman treat alternate cases with and without penicillin, when I feel sure that they will soon abandon its use.—I am, etc.,

Northampton. L. HOYLE.

Treatment of Ringworm of the Scalp

SIR,—The paper by Drs. H. Haber and R. T. Brain and Mr. J. W. Hadgraft on the treatment of ringworm of the scalp (September 17, p. 626) raises many important questions, particularly in connexion with the mode of action of preparations containing fungicides. Since similar results were obtained with phenylmercuric nitrate and with salicylanilide, it is deduced that "it is not the fungicide which effects the cure but the penetrating power of the bases employed" (carbowax in the cases described).

This view is not, however, in accordance with the results we have obtained in a recent investigation concerned with 261 cases of ringworm of the scalp due to *Microsporon audouini*. Using three different fungicides in carbowax, cures ranging from 38% to 74% were recorded. The mode of action of fungicides is undoubtedly complex, and whether treatment with such compounds is necessary after *x*-ray epilation is controversial. Brain and his colleagues state that "*x*-ray epilation has to be followed by the application of a fungicide." Lydon, Stephanides, and Robb[1] have reported cures in 103 cases by *x*-ray epilation without the application of fungicides. We are fully in agreement with the statement that the hair itself resists penetration of reagents, but we have not been able to find evidence that carbowax is capable of softening the hair or loosening the connexion between the hair and the hair papilla.[2]—We are, etc.,

University Degrees

SIR,—I have been most interested in the views expressed by your correspondents on medical education, and wonder if you would consider printing some comments from a London clinical student who held senior officer rank in the late war and is somewhat older than his fellows.

While agreeing that the present multiplicity of qualifying degrees and diplomas, all of them more or less of the same standard, is most illogical and should be simplified, it seems a lot to hope that the universities, colleges, etc., will settle their differences before the Greek Calends, and meanwhile the non-university student graduating into the National Health Service is seriously handicapped.

I refer to the point (brought out by one of your correspondents) that none of the higher appointments in the profession, as it is at present being reorganized, is open to those who do not hold the M.D. or M.S. *in addition* to the M.R.C.P. or F.R.C.S. Now, although the university graduate is allowed by the Colleges to sit for the membership or fellowship without insisting that he take all their previous examinations, the qualified Conjoint man must in the case of London University (whose external regulations are the least exacting in this respect) go back to dissecting a frog and doing elementary physics and chemistry and all the other examinations for the external M.B. before being permitted to sit for a higher degree. There must be few indeed with either the time or money to waste in performing such a feat, and surely it is questionable whether it is desirable to employ a qualified man's time in undertaking such a pursuit.

On the other hand, I quite understand the natural reluctance of any university to cheapen its higher degrees—it would both lower the standard and discourage people from taking the initial M.B. But at the same time it must be admitted that it is very unfair for the brilliant Conjoint student to be perpetually condemned to a secondary position *vis-à-vis* his university colleagues as far as senior hospital appointments are concerned. This point, I should like to stress, has arisen in a particularly acute form since the institution of a service where higher degrees and diplomas are going to win promotion to the highest posts and which we should all enter without handicaps and with equal chances for our talents.

I therefore beg to suggest that London University (let it be hoped soon followed by others), through its national position and the fact that it possesses an external department, should take the lead in allowing any man or woman qualified in this country who is a matriculated student of the university and has spent at least three years in a medical teaching institution approved by the university to take a qualifying examination, which might consist of part or the whole of the M.B. finals, and which would in no sense confer a degree in itself but would allow successful candidates to go up for a "special" M.D. or M.S. degree later.

I feel that this might be a reform which could be put through with the least disturbance to existing institutions, and therefore that it might stand some likelihood of being adopted in time to be of some use to the students of to-day (many of them non-university simply because they are ex-Service), who feel a sense of frustration at qualifying into a nationalized profession with the highest posts permanently denied them however keen or able they may be.—I am, etc.,

London, S.W.3. E. O'C. TANDY.

Cigarette Cough

SIR,—I wonder if any of your readers have any views to express on the above subject. I have frequently been called on to differentiate between genuine cigarette cough and cough symptomatic of disease, and have found the following points of considerable help.

(1) A cigarette cough, though it sounds distressing, especially when well established, does not cause any distress; as soon as a fit of coughing is over the subject continues to breathe quite normally and without any noticeable acceleration of the respiratory rate. (2) Though the cough may have a moist quality it is not usually productive, unless the subject has a cold or other catarrhal condition of the respiratory tract. (3) The cough is invariably brought on by the first cigarette in the morning. (4) It is noticeable that very many heavy cigarette smokers who inhale steadily have little or no cigarette cough, while very frequently non-inhalers are severely afflicted. I believe that this is explained by the fact that non-inhalers are more prone to the habit of leaving the cigarette in the mouth while smoking. This means that while they may not inhale the filtered smoke pulled through the cigarette they are continuously inhaling the hot, unfiltered smoke trailing up from the tip, the irritant nature of which will be appreciated by anyone who has had the misfortune to sit beside an inconsiderate smoker at the pictures or the theatre.—I am, etc.,

Cavan, Eire. B. J. GALLIGHAN.

Diabetes and Gout

SIR,—Your leading article on diabetes and gout (September 24, p. 692) contains certain questionable statements which might mislead some of your readers. It is said that "in 1909 Ascoli and Izar showed that dog's liver contained an enzyme which converts uric acid to dialuric acid, so that probably uric acid can be converted into dialuric acid in man." The facts, however, are that dogs possess an enzyme, uricase, which converts uric acid into allantoin, but that neither this nor any other uricolytic enzyme is present in human tissues, which are unable to convert uric acid into any other substance.

Regarding experiments on birds, pigeons are alleged to have died "from a deposit of sodium urate over all the serous surfaces." Surely the inference should be that an inflammatory condition of these surfaces was associated with deposition of urates on them, but the cause of death is not evident. In general, results obtained for one species, or even sub-species, of animal cannot safely be extrapolated to other species, and this is particularly the case for purine metabolism. While there certainly appears to be a case for connecting rheumatoid and possibly gouty arthritis with steroid metabolism, the evidence presented is insufficient to establish any connexion between human diabetes and purine metabolism.—I am, etc.,

London, N.W.6. R. TRUSCOE.

Dysentery in Monkeys

SIR,—Until recently monkeys intended for experimental work were of necessity imported by sea. Recently, however, large numbers of the common rhesus monkey, *Macaca mulatta*, have been imported by air from India, and many have been re-exported to the U.S.A. after only a few days in this country. A high mortality among the animals was usual during the sea voyage, but this is much reduced by air travel. By this route a death rate of 2% is considered high by the airway companies.

However, the shorter time spent on the journey implies that a higher proportion of sick animals arrive in England, and some may well be carriers of infectious disease. Recently we have seen three outbreaks of clinical dysentery in such monkeys awaiting re-export and have isolated from them *Shigella flexneri* type 103 Z, as reported by us from these animals in 1948.[1] Another animal with the same infection was procured from a commercial dealer, but its method of import was not stated. From yet a fourth outbreak we have isolated *Shigella schmitzii*. Human infection with *Shigella flexneri* type 103 Z is rare in this country, but it appears to be more common in the U.S.A. However, we feel that a hazard exists. Spread of *Shigella schmitzii* from apes to their keepers was recorded by one of us in 1949.[2]

British Overseas Airways Corporation are fully cognizant of this matter and have already instituted control measures, both on the aircraft and at airports, to prevent any spread of such infections either to the aircrew or to those handling the animals during loading and unloading or while tending them during any stops.—We are, etc.,

POINTS FROM LETTERS

Resisting Pain

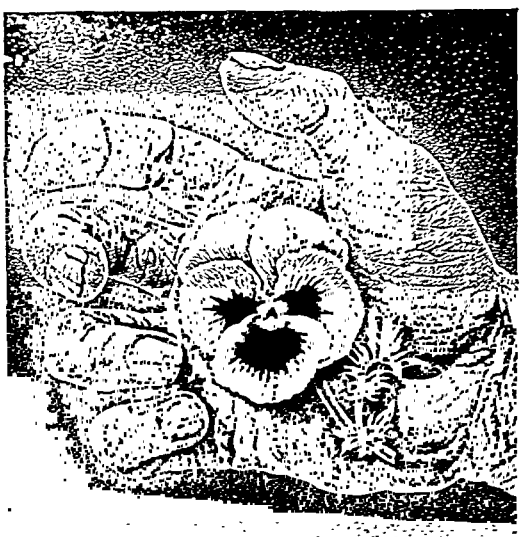
Dr. R. MACDONALD LADELL (Edgbaston, Birmingham) writes: Mr. Charles Davy's comment (September 24, p. 709) on the excellent article by Dr. E. B. Strauss (August 20, p. 411) reminds me that a few years ago I embarrassed my dentist (since deceased) by insisting that he should draw four well-rooted molars in succession without using any anaesthetic whatever. I am not a masochist. My main reason was the spiteful one that I heartily disliked the dentist as a man, though respecting his professional abilities. Every psychologist will appreciate that point. My other reason was to test my theory that pain when understood and accepted because it serves some end can have a tonic effect. Certainly I experienced no sense of shock and came away with a sense of well-being. This last of course may have been due to the fact that I was feeling pleased with myself. Is it not possible, however, that we make too much of a bogy of pain?

The Use of Experience

Dr. DAVID WHEATLEY (Twickenham, Middlesex) writes: In his article (September 24, p. 663) Sir Heneage Ogilvie rightly condemns the narrowness of outlook which may be produced in some by specialization. Yet does he not fall into the same error himself? Later, referring to the hollow needle, he observes that "it must bear the responsibility for spinal anaesthesia." This would seem to reflect upon the latter procedure and must surely be a personal opinion. And would he agree that the woman with severe hyperemesis gravidarum, to quote but one example, is "rejecting what is harmful or surplus to requirements [of her tissues]"? Even taken in its context I find it hard to reconcile such a sweeping statement with the objects of the article, although I may be biased through reading it with a physician's outlook.

IN BRONCHIAL ASTHMA

1600: *"The specifics commonly used for moist asthmas are the roots of Cuckowpint, Hyssop, Horehound . . . . the syrup or volatile salt of Tobacco; Gum Ammoniac (above all) dissolved in vinegar. Compound Spirit of Verdigrise, dulcify'd Spirit of Nitre, Turpentine . . . . Balsam of Sulphur . . . . Juice of Woodlice with wine (an incomparable medicine) and the carminative spirit if the stomach be disordered."*



MICHAEL ETMULLER, *Professor of Physic, Leipzig*

Today: The "incomparable medicine" in bronchial asthma is 'Neo-Epinine.' Patients obtain relief without the discomfort of repeated injections, the side-effects of adrenaline, or the sleeplessness of ephedrine medication. 'Neo-Epinine' is administered sublingually as a compressed product or by oral inhalation as Spray Solution.

'NEO-EPININE'

ISOPROPYL*nor*ADRENALINE SULPHATE

THE GENTLE GIANT

'Albucid' Soluble in Ocular Therapeutics

FOR TISSUE of the highest sensitivity it is essential that local chemotherapy be affected by agents free from irritation. 'Albucid' Soluble Eye Drops are adjusted to pH 7.4 and are thus free from irritating alkalinity. High therapeutic efficiency, combined with ready solubility and very low toxicity, makes 'Albucid' Soluble the agent of choice in most eye infections. 'Albucid' Soluble Eye Ointments, containing 'Albucid' Soluble in a neutral cream base, are available for the treatment of infections of the eye and lids, where a slower and more prolonged absorption may be considered advantageous.

'ALBUCID' SOLUBLE

SULPHACETAMIDE SODIUM

EYE DROPS 10% and 30% in bottles of ½ oz.

EYE OINTMENT 2½%, 6% and 10% in tubes of 60 grains and 25 grams.

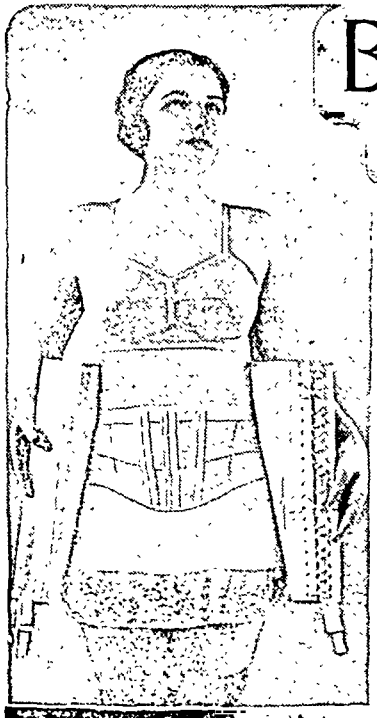
LONDON HOSPITAL CATGUT

(Morley's Process)

AND



TENSILE STRENGTH

THE self-imposed arbitrary standard set for London Hospital Catgut at its inception is above that of the B.P. Codex and the U.S.A. Pharmacopoeia. **The London Hospital standard has never been departed from and is still maintained.**

This outstanding feature, together with an elasticity (elongation) approximating 40%, affords the Surgeon perfect safety in using **fine sizes** compatible with modern technique.

When using **London Hospital Catgut** we **strongly recommend Surgeons to use B.P.C. sizes** 2/0, 0, and 1 for general surgery and B.P.C. sizes 3/0 and 4/0 for very fine work.

"FOR THIS RELIEF MUCH THANKS..."

HAMLET, ACT 1, Scene 1.

Francisco's remark can find ample application in everyday usage and might well express the feelings of those who have obtained rapid relief from PAINFUL SPASMS of smooth-muscled organs.

Spascol REGD.

Contains an important new synthetic anti-spasmodic, offering outstanding advantages over papaverine in the symptomatic treatment of SPASMS AND SPASTIC DYSMENORRHŒA.

1. RAPID AND PROLONGED THERAPEUTIC ACTION. (1 tablet taken orally gives prompt relief, lasting from 3 to 6 hours).
2. NON-HABIT FORMING.
3. WELL TOLERATED.
4. EFFECT IS MAINTAINED BY A SMALL DOSE.

Packings of 10 tablets.

Samples and Literature on request

FORMULA : Each tablet contains 1—(3 : 4 : 5, triethoxyphenyl)—6, 7—dimethoxy-isoquinoline, 0.04 gm. ; Hyoscina Hydrobrom, 0.0001 gm. ; Ext. Belladonna, 0.001 gm. ; Rhizome, Rhei, 0.005 gm.

Obituary

MAJOR GREENWOOD, D.Sc., F.R.C.P., F.R.S.

Major Greenwood, professor emeritus of epidemiology and vital statistics in the University of London, who died suddenly in London in his seventieth year, on October 5, was for more than a generation one of the outstanding figures of the day, both in his chosen field of medicine and among statisticians in this country and throughout the world. Though there is no doubt that he became the leading authority on medical statistics, at such a description he might himself have smiled sardonically, for throughout his career he was no respecter of authority, no lover of "expert witnesses," no accepter of *ex cathedra* statements. Indeed, in a somewhat "left-handed" way he had an abiding affection for the amateur in science, the amateur with no reputation and no technical tricks at his command, but with a questioning mind, a fund of common sense, and above all an intellectual honesty of purpose. It was such characteristics, probably, that made so dear to him John Graunt and his "shop arithmetic" on the seventeenth-century bills of mortality, and at a later date his great hero William Farr, who with the simplest of approaches built so firmly our English system of vital statistics, and so equally simply displayed its value. Though an able practical mathematician, Greenwood never lost this love of simple statistical tables or of what he himself invariably called "little sums."

Major Greenwood was born in 1880, the only son of a general practitioner in the East End of London. He was educated at Merchant Taylors' School, from which he went for his medical training to the London Hospital. On qualifying in 1904 he was appointed demonstrator of physiology in the London Hospital Medical College, where Leonard Hill had taken up the professorship. Here he was associated with Hill and his early work on caisson disease. During these years his mathematical leanings led him to University College, London, to study the then newly developing science of mathematical statistics under Karl Pearson. For these two men of international and lasting reputation, masters in very different fields of science, Greenwood never lost his early feelings of admiration and attachment. With both medical and statistical crafts now at his command he was in 1910 appointed statistician to the Lister Institute, and began to publish the long series of studies of vital statistics which were the foundation of his later career—studies, for instance, of infant mortality, of marital infection in pulmonary tuberculosis, of hospital mortality rates from pneumonia. Here, too, he made detailed investigations of the epidemiology of plague in India, working alongside Arthur Bacot, one of his most intimate friends, whose early death was a blow from which he never wholly recovered. Though on the staff of the Lister Institute till 1919, the first world war naturally redirected his activities. He took charge of a medical research subsection of the Ministry of Munitions and became immersed in the problems of hours of work, of the dietaries of munition workers, of the incidence of tuberculosis in the industrial community, and, lastly but probably the most remembered to-day, the incidence of repeated accidents in factory workers or what became known as "accident proneness." In this work he collaborated with Udny Yule.

These years led also to his association with Professor E. L. Collis and their joint book, *The Health of the Industrial Worker* (1921), and, more indirectly and some years later, to the Medical Research Council's Statistical Committee, which was a descendant of the wartime committee on the Health of Munition Workers. Greenwood became first chairman of the statistical committee, a position he held till 1948, and, aided by the members of the committee, the Council's statistical staff that he had gathered round him did much to raise the standard in the presentation and use of statistics in medical publications. At the end of the first world war he left the Lister Institute to take charge of medical statistics at the newly established Ministry of Health, where he worked in close association with Sir George Newman, the first C.M.O. Here his deep interest in historical epidemiology became increasingly apparent not only in his published papers but also in many unsigned contributions to Ministry of Health reports which unmistakably bear his mark—for example, that on the 1918 influenza epidemic. How he found time for it all is difficult to see, but he was a man of few interests outside reading, and he read late and early—not only indeed within his subjects but roving over the whole field of literature, modern and ancient, and with a phenomenal memory that allowed him to quote largely and at will—with Latin in the original as a mere sideline. So at this turning-point of his career there were papers on Galen and on Sydenham, on the fertility of the English middle classes and the vital statistics of Sweden, on the natural duration of cancer and the vital capacity of young healthy males, many of these papers, naturally, in collaboration with other workers.

From the Ministry Greenwood moved in 1928 to his final position—Professor of Epidemiology and Vital Statistics in the newly created London School of Hygiene and Tropical Medicine, a chair he held till his retirement in 1945. Here, though in fact its beginnings came a year or two earlier, he entered upon that long and productive phase of work in association with his colleague W. W. C. Topley, the School's professor of bacteriology and immunology, in their study of experimental epidemiology or, as Greenwood once wrote, the attempt "to mould a little epidemiological world of our own nearer to the heart's desire" in the hope of elucidating the laws of the epidemic rise and fall of disease. Though fifteen years of work did not allow them to give a precise quantitative expression to the law of development, it threw much light on epidemic occurrences and on such practical issues as the limitation of protection by inoculation. Here, for example, arguing from mouse to man, it seemed that artificial immunization could be of great value for a short or discontinuous period of even severe exposure but would not avail against a long-continued exposure to a very unfavourable environment. At this time, too, Greenwood developed an interest in the growing subject of psychology, and, collaborating with his colleagues Dr. May Smith and Professor Millais Culpin, both read and wrote thereon. He had also his teaching duties to perform—directed almost entirely to postgraduate students sitting for the University's diploma in public health. In the preface to his Herter lectures, "Epidemiology, Historical and Experimental," delivered in Baltimore in 1931, he expresses his

conviction "that the history of ideas is an essential part of the education of both public health officers and laboratory workers," and this view ran clearly through his lecture courses.

The student in search of "facts," to be transferred from the lecturer's notebook to the student's notebook "without passing through the mind of either," would find Greenwood of little help. He was not at his best either in teaching statistical methods—they came much too easily to him to allow him to appreciate the difficulties of others. But only a very mediocre student could sit through the course of lectures which he subsequently published under the title of *Epidemics and Crowd Diseases* (1935) without feeling an inspiration, a fascination which would long outlast a mere examination. In his final years Greenwood renewed his historical studies—perhaps, like many of us, as a temporary escape from the realities of the day during the second world war. These resulted in his Heath Clark lectures on British pioneers of social medicine.

Major Greenwood was elected a Fellow of the Royal College of Physicians in 1924—he had given the Milroy lectures in 1922; was awarded the Buchanan Medal of the Royal Society in 1927 and elected a Fellow in the following year; was honorary secretary of the Royal Statistical Society from 1919–34, its president in 1934–6, and, in 1945, one of the rare recipients of its gold medal; he served on the Senate of London University and on many of its committees. Many persons who never met him must have known him through his writings, for apart from the flow of scientific papers he wrote many articles and letters in this and other journals. They will have realized that he was a forcible fighter for what he believed to be right, and that his command of epigrammatic incisive English and his satirical wit made him an opponent that no one would lightly seek to provoke. He may thereby have inevitably discouraged some from entering the statistical field, one in which the way appeared so hard—but that is a risk that must be run by every medical statistician with an urge to raise the standard of what Greenwood once called "arithmetic guided by logic." Many others he must have encouraged and inspired, both by his zeal for accurate observation and clear presentation and by his unchanging belief in the importance of statistical methods in medicine, a belief which he lived to see widely accepted.

Sir Robert Hutchison writes: I first got to know Major Greenwood when he acted as one of my clinical clerks at the London Hospital about forty-six years ago, and was at once impressed by his keen intelligence. Although his father had been a general practitioner, he himself never attempted to practise. He felt probably that clinical work was not really his *métier* and he could never have acquired what is called a bedside manner. He took instead to the study of epidemiology and medical statistics, for which kind of work he was well suited by the penetration and accuracy of his mind and by his fondness, as he often put it, of "doing sums." There were some, I know, who thought him cynical and censorious, and to some degree they were right. He certainly had a poor opinion of modern man, and he had too much intellectual integrity to have any patience with stupidity. He could, indeed, be a devastating critic and controversialist, while his voice and expression were apt to make him seem supercilious. Those who knew him best, however, realized that much of his acerbity of manner and lack of geniality was really due to shyness and that he was as stern a critic of his own work as of that of others. It is true that he did not wear his heart upon his sleeve, but to the few whom he admitted to his friendship he was entirely loyal, and would send them long typewritten letters, sometimes weekly, in which he discussed anything and everything in his rather astringent style and with the frequent use of italics which was characteristic of him. Essentially, indeed, he was modest and unassuming; his foes were pretentiousness and pomposity, and these he fought with a rapier-like wit. He was by nature rather melancholy and, since the death of his wife, lonely. When he spent a week-end with me two or three months ago it was evident that he neither wished nor expected to live much longer, so doubtless death came to him as a friend and, as he would have wished, unheralded.

Dr. Millais Culpin writes: Perhaps only Greenwood's intimates could understand his curious blend of formality and good fellowship, and how even his humour demanded the precise word and the rounded phrase. He played a pretty game of chess, failed to reduce bridge to a mathematical formula, and reverenced piquet as the relic of a gracious past. Up to the end he visited a 90-year-old neighbour once a week, to cheer her up by playing with her a card game that only they understood. Unexpected doings like this last surprised those who knew only what seemed a rather formidable academic personality. Some have thought that he selected statistics as his life's work because that branch of medicine was most remote from the emotional. Perhaps they were right; he was a sensitive soul and often found refuge in doing sums, though the human meaning might still intrude. He once said he never knew till he visited that city why the death rate of Ditchworth was so high, but when he came out at the railway station he could see that no one there would wish to grow old. "And," he added, "I explained that to the city fathers before I left." He could be very blunt to his closest friends if he thought the occasion demanded bluntness. Indeed, he might seem to say that because he was one's friend he expected one's standard to be as high as his. He confided to me, after his return from a trip to America where he delivered some academic lectures, that he had scruples about accepting a fee for them. Some of the staff in his department at the School were Civil Servants, not very well paid, and they couldn't take time off for a holiday in the States and get extra money for it, so he was planning a subtle holiday-equalization fund to ease his conscience. He read many books in divers languages and had an old-fashioned facility for the apt quotation. With his literary memories at his command, on a country holiday he could give the stories of most of the people that had mattered in local history, bishops and agriculturists in particular. Although he might spend a week-end with a newspaper lord or go on some public errand to Geneva, he found satisfaction of his social needs chiefly in academic circles, and he had a deep-rooted pleasure in his association with the University of London. In discussing some matter of university policy with me he once said, "Remember, I was brought up in the Hackney Road—and you weren't far off." I had then known Major Greenwood for nearly half a century and I felt that we understood each other.

Dr. Charles Singer writes: I should like to send a tribute to the memory of my old friend and colleague, Major Greenwood. There must be very few members of our profession with such wide accomplishments. Your pages have for many years given evidence of his lively and felicitous style and not least in his article on "A Cholera Centenary," which appeared last week. Greenwood possessed an extremely exact mind. His accurate scholarship gave point—often somewhat painful point—to an exceptionally

ready and often mordant wit. Long ago I learned to regard as final his judgment, when he cared to give it positively, on any point of scholarship. How he succeeded in his busy and academically eventful life in acquiring such facility and accuracy in both mathematical and classical disciplines has always been a mystery to me. His learning had about it an almost uncanny element. It was often my honour and privilege to discuss with him matters of scholarship. I cherish the memory of these many meetings, but most of all I cherish the memory of being associated with him in his establishment of the first organization to assist scholars driven from their homes by the German Nazis. In this most successful venture he appeared at his very best as a humane physician and a lover of every form of learning. Despite his formidable humour, Greenwood was an extremely kind-hearted man and he hated every form of unfairness and injustice. I saw him at his gallant best as the effective mover for the foundation of the Academic Assistance Council (later the Society for the Protection of Science and Learning) in 1933. From that time on he served its cause—the salving of learning in a war-ridden world—with all his might, and he acted as treasurer of the society to the end of his life. He was thus the agent in preserving for civilized posterity the work of innumerable important scholars, thinkers, writers, and scientific investigators. In dealing with the complicated and difficult affairs of these unfortunate carriers of civilization he always showed them the utmost personal consideration, and no trouble was too great for him to take on their behalf. The world of learning owes him a very deep debt. Many hundreds of scholars all over the world will mourn the loss of this great-hearted, far-sighted, valiant little man. His life and bearing have lent a nobility to learning that could not fail to be recognized by all who knew him. The entire intellectual life of the next generation will be the richer for what Greenwood has done for it. He was personally a retiring and rather withdrawn man, and it may be that this great service will be forgotten; but it was none the less very real and effective, for Greenwood was a most determined and vigilant watchdog of civilization against the attacks of barbarism.

AUGUST KROGH, Ph.D.

Professor August Krogh, the famous physiologist, died on September 13 at his home in Copenhagen. He was 75, and had been ill for some time. Professor Krogh won the Nobel Prize in physiology and medicine in 1920. He had held the chair of zoophysiology in the University of Copenhagen from 1916 until his retirement in 1945.

We are indebted to Sir Henry Dale, O.M., for the following appreciation: In no country outside his own was Krogh more intimately known, or held in higher regard by workers in his own chosen field of science, than in Britain, where he made some of his closest scientific and personal friendships. He was a frequent visitor to this country, and when he came to a meeting of the Physiological Society he came as an ordinary and always welcome member. Krogh did not study or qualify in medicine; like some of our own most eminent contributors to physiological science, in particular some of the Cambridge school, his approach was from the side of general biology, and without immediate concern for specifically medical problems. It is hardly necessary to add that he was led by that route to studies of the highest medical interest and importance. He graduated at Copenhagen in zoology in 1899, but from 1899 to 1908 he was assistant in the department of physiology of the Copenhagen medical school, under the late Professor Christian Bohr. It was under Bohr that he had his first experience of research and acquired his interest in the study of the blood and of its function as a carrier of the gases connected with respiration. A communication of his work in this field to the International Congress of Physiology at Heidelberg, in 1907, first brought Krogh and his work to wider notice and made contacts for him with the late J. S. Haldane and with his own near contemporary, the late Sir Joseph Barcroft. Krogh's last visit to England, in 1948, was to take part in a conference at Cambridge on haemoglobin and its properties, held to commemorate Barcroft and his work.

Krogh's activities as a research worker, devoted to physiological problems of many kinds and over a wide range of animal species, have enriched physiological knowledge in a number of its departments. His fundamental work on the contractile and other functions of the capillary blood vessels brought him the award of a Nobel Prize in 1920, and was fully presented in a monograph, embodying his Silliman Lectures at Yale, in 1922. A little later he was concerned with the introduction of insulin to Denmark and the establishment of its manufacture there. He published other monographs on osmotic regulation in aquatic animals and on the comparative physiology of respiratory mechanisms. Having retired in 1945 from the university chair of zoophysiology, which he had held since 1916, Krogh was given a special appointment and provided with a small research establishment in the basement of his house in Gentofte, in the environs of Copenhagen. Here, until his last illness, he was happily at work in a relatively new field of investigation dealing with the special physiology of insects. For this purpose he was receiving a regular supply of live locusts by airmail from the international research centre on locust control in our British Museum of Natural History at South Kensington. To study the contractile activity and metabolism of locusts in flight he had constructed a light and delicately pivoted merry-go-round, which could be driven by the flight of attached locusts in such rapid rotation that they could be observed only by stroboscopic illumination. The work was already yielding new and important items of physiological knowledge, and it is sad to think that the guidance and inspiration of Krogh's special genius should be lost to it at so early a stage.

Krogh received many public recognitions, including several from Britain. The Royal College of Physicians of London awarded him its Baly Medal, while the Royal Society made him one of its limited group of Foreign Members in 1937 and appointed him to give its Croonian Lecture in 1940, though the war prevented its delivery till 1946. Krogh had a quiet and rather shy personality, with a jerky manner which did not obscure his warm friendliness or his ever ready response to humour. Like all loyal Danes, he suffered greatly in spirit under the German occupation, though, more fortunate in that than some of his colleagues, he escaped direct or physical ill-treatment. The experience seemed to make him only the more eager to renew ties of international friendship, and especially those with colleagues in Britain, by whom his memory will long be cherished in affection and esteem.

ROBERT MILNE, M.D., M.S., F.R.C.S.

Robert Milne, consulting surgeon to the London Hospital, died suddenly while on holiday on September 29 at the age of 68. He was born in 1881, son of Dr. Robert Milne, of Inverurie, and educated at the City of London School, joining the London Hospital as a medical student in 1899. In addition to an entrance scholarship he carried off scholarships in anatomy, physiology, and chemistry as well as many prizes. He qualified in 1904 and graduated M.B., B.S. a

year later, proceeding M.D. in 1907. After qualifying, Robert Milne held practically every house appointment there was to hold, house-physician, house-surgeon, receiving-room officer, resident accoucheur, with in addition assistantships in the departments of pathology, ophthalmology, oto-rhinolaryngology, and orthopaedic surgery. On this solid foundation of general training, and after taking the F.R.C.S. in 1906, he began, with his appointment in 1908 as surgical registrar, to build his surgical career under the aegis of Rigby and Furnivall. Appointed assistant surgeon to the London Hospital in 1910, he was surgical tutor and teacher of elementary clinical surgery from 1914 to 1920. During the 1914–18 war he served as a major in the R.A.M.C. in France and Italy. In 1922 he became a full surgeon to the hospital and assumed responsibility for the orthopaedic department—and with it the mantle of "Tommy" Openshaw. Between the wars, in addition to a busy consulting practice he was constantly in demand in the courts for an opinion in accident cases. He was consultant surgeon to Dr. Barnardo's Homes, a post to which his father, long associated with Dr. Barnardo's, had the joy of welcoming him officially. He examined for the Royal College of Surgeons, the Society of Apothecaries, and the University of Cambridge. With all this he was assiduous in his attendance at "the London" and was an inspiring teacher. In 1942 Robert Milne retired and was appointed consultant surgeon. But though ceasing active work at the hospital he was still active in mind and body. He had been civil consultant in orthopaedics to the Royal Navy since 1939, so on his retirement, nothing daunted, he shaved off his moustache and reappeared in the uniform of a surgeon rear-admiral and spent the remainder of the war devoting his considerable talents to the welfare of the Royal Navy.

Robert Milne was a most lovable character. Kindly, good-tempered, approachable, he was the soul of courtesy, and the one thing that moved him to wrath was discourtesy in any form. He had an impish sense of humour and an endearing propensity to kindly leg-pulling. As an orthopaedic surgeon he was conservative, having, one felt, in the course of his wide experience seen almost all the mistakes of over-enthusiasm. But his tidy, accurate, unhurried, and calm technique was an object lesson; his knowledge of the details of almost every form of human labour, which he applied with uncanny judgment to the problems of the partially disabled, was encyclopaedic; his memory for clinical details was astonishing. As a teacher he had the rare gift of imparting judgment as well as facts to his hearers, and his clinics were always packed to overflowing.

Apart from his work and the hospital his one absorbing interest was his family, with perhaps, coming third, an example of his impish humour which his son has described as "a leaning towards the collection of improbable trifles." One suspects that the interests in the byways into which the hunt led him, and in the people that he found there, were the real attraction. "Bobby" Milne's loss is a sore one. He leaves a widow, two sons, and a daughter, to whom the sincerest sympathy of all who knew him will be extended.—O. J. V.-J.

Sir Henry Souttar writes: The loss of Robert Milne will be deeply felt by those who were fortunate enough to be his friends and his colleagues. A quiet unassuming man whose one real interest was in his work and in his patients, he gave devoted service to the hospital which was the centre of his life. His shrewd common sense, not untinged with humour, won the confidence of both his patients and his students, and in every corner of the Commonwealth there are surgeons who owe to Milne their initiation into the correction of deformity. With an obstinacy so characteristic of his countrymen he refused to be divorced from general surgery, but his real affection was for orthopaedics, and in the handling of bones and joints he had a skill and an insight which came from long experience as well as a natural instinct. It was perhaps as an examiner that one saw Milne at his very best, for no one had greater skill in extracting the best from a candidate. He was a good fellow, and many will miss his cheery presence.

H. H. B. writes: Robert Milne, known to most of his friends and colleagues as Bobby, was the son of a deeply loved and respected general practitioner in Bow, an upright man with an unswerving belief in porridge and family prayers and much of the Roman *gravitas* that was so characteristic and, being mellowed by his deep kindliness, so comforting and inspiring a quality in Bobby himself. So far as any man can judge another, Bobby was never ruffled by anything. There was an invisible and infectious serenity in his speech, gait, and all his actions. He published little, but his judgment was seldom, I should imagine, at fault, and personally I never found it so. He was a careful and extremely competent operator and never in a hurry to operate if other measures, in his opinion, could profitably and safely be given a chance. We were friends from the day we first met in the dog-fish and frog-dissecting stage of our education, and if there are not, alas, very many survivors from that period there must be thousands of younger men who will be feeling the loss of one of the kindest and staunchest of companions, teachers, and helpers in every sort of trouble.

Dr. William George Simpson Thomson, who died on September 20 at the age of 62, had been deputy medical superintendent at Cheadle Royal for twenty-seven years. He was educated at Aberdeen, where he graduated first in classics and as M.B., Ch.B. in 1911. He took the D.P.H. in 1914 and the D.P.M. at Manchester in 1925. After a period as house-physician in the Aberdeen Infirmary he was for a time assistant medical officer at the county mental hospital at Cheddleton, Staffordshire, where he had considerable experience in mental disease. He was also a neurologist to the pensions boards set up after the 1914–18 war. In 1922 he was appointed senior assistant medical officer to the Manchester Royal Hospital, Cheadle, and two years later he became deputy medical superintendent. For many years Dr. Thomson was visitor to the licensed houses under the Mental Deficiency Act for the City of Manchester Courts. He was a member of the Royal Medico-Psychological Association and acted as an external examiner for the University of Manchester. He was a good general neurologist, and his advice was often sought on the diagnosis and treatment of functional and organic diseases of the central nervous system.—E. M. B.

Mr. Harry Freeman died on September 29 at a time when he had just attained his ambition of devoting his life to surgery. Born in 1894, he obtained an entrance scholarship in anatomy and physiology at King's College, London. He became a member of the Pharmaceutical Society, and by working as a dispenser in the evenings he earned money to help pay his hospital fees. He had a distinguished career at the Westminster Hospital, where he won the Bird gold medal and prize, the Chadwick prize, and the Sturges prizes for clinical medicine and surgery. He qualified in 1921, and after a resident appointment

two important aids in infant care

BABY LOTION *— for nappie changing and skin irritation*

BABY POWDER *— for use after every bath*

Johnson's Baby Lotion for the routine care of infants' skin has already received wide medical support. A smooth, white, antiseptic oil-in-water emulsion, it reduces effectively surface bacteria, urine irritation, and other types of rash. Together with Johnson's Baby Powder, these are two important products every mother needs in the care of her baby.

as casualty house-surgeon at the Westminster Hospital he went into general practice in Dalston. Freeman's personality and skill soon brought him a large and busy practice, but he found time to keep in contact with hospital work at the Prince of Wales Hospital, Tottenham, where he held a series of clinical assistantships. In 1932 he obtained the diploma of master of midwifery of the Society of Apothecaries, moved to the West End of London, and practised midwifery. Six years later, at the age of 44, he passed the primary examination for the F.R.C.S., and he became a Fellow in 1941. By a stroke of good fortune he was able to perform surgical operations with a senior acting as his "assistant" during the war years. He took every advantage of this opportunity and soon became a competent surgeon. As an associate lecturer on surgery at the North-East London Postgraduate College he helped undergraduates who had failed in surgery at their first examination to pass at their second attempt. During the whole of the war he and his wife were in charge of an air-raid casualty centre in Holborn, and they were both on duty at this centre every night. He also operated on air-raid casualties at the Royal Albert Dock Hospital. Sir Hugh Griffiths has paid tribute to him as a "skilled and kindly surgeon and very gallant gentleman." Harry Freeman was appointed assistant surgeon to the National Temperance and Albert Dock Hospitals in 1946. Subsequently he studied gastroscopy under Mr. Hermon Taylor and published original articles on this subject. He also wrote a section of a book on gastroscopy which is in course of publication. His courage, strength of character, hard work, and great ability, which enabled him to conquer his early difficulties, will remain an inspiration to his friends. He leaves a devoted wife, who is in active medical practice, and two daughters, who are married and live abroad.—W. E. T.

Dr. Donald Campbell died on June 19 at his home near St. Helens, Lancs, at the age of 66. Dr. Campbell qualified in Dublin in 1915. He had been in general practice in St. Helens since 1919, and his sudden death came as a shock to his colleagues, since he had been working right up to the last. In 1928, while still in practice, he took the M.R.C.P. During the 1914–18 war Dr. Campbell served first of all as a combatant in the Indian Army and was later transferred to the R.A.M.C., serving in France, where he was wounded. During the recent war he was a medical officer for the local Home Guard. Dr. Campbell had studied in the School of Medical History at Oxford, and he was the author of *Arabian Medicine and its Influence in the Middle Ages*. He had always been interested in medico-political work and was honorary secretary of the local panel committee from 1924 onwards. He was chairman of the St. Helens Insurance Committee from 1933 until 1948, when he became vice-chairman of the local executive council. Dr. Campbell was always a helpful and agreeable colleague, and he will be sadly missed by his patients and his friends in the St. Helens area.—A. A. W. M.

Dr. Janet Young Laidlaw died on August 9 at the age of 66 after a long illness. She was a student at the London School of Medicine for Women, and qualified in 1931. She graduated M.B., B.S. two years later, and was for a time a resident house-physician at the Royal Free Hospital. Thereafter her professional work was mainly among children. She was school medical officer in Cambridge until increasing ill-health enforced her retirement just over a year before her death.

K. F. writes: I first knew Janet Laidlaw when we were students together over 20 years ago. She was then in her late thirties, for her opportunity to study medicine had only just arrived. Her determination and tenacity were almost hidden by her quiet and unobtrusive manner. She did not seek knowledge, or skill, or advancement for her own ends, but because she cared about the needs and the rights of others. Humility, integrity, charity—those of us who knew her and loved her know that she measured up to the true meaning of these old-fashioned words. Outside her work among the children whom she loved and understood her interests were in her own folk, in her garden, and in the little house in Galloway to which she turned whenever she could and which she had made into a haven of rest and peace for her friends.

Medico-Legal

DOCTOR CENSURED

TRIBUNAL FINDINGS

A Tribunal set up under Section 42 of the National Health Service Act recently considered a case which was reported in these columns (June 4, p. 1009) when it came before the Medical Services Committee of the West Sussex Executive Council. At the hearing both the complainant and the respondent medical practitioner were legally represented.

The Tribunal found as facts that the doctor, when he attended the infant whose father made the original complaint, "was under the influence of alcohol to such an extent that his professional judgment was impaired"; and that on the night in question the doctor had failed to notify his partner of his intention to be away. Though the respondent might have arrived at the house with greater promptitude than he did, it could not be said that the delay in his arrival was unreasonable or excessive. The doctor then examined the child, failed to appreciate that it was gravely ill, failed to prescribe any treatment for it, and left the house about 10 minutes after he had arrived. Within the next half-hour the child died. The doctor admitted before the Tribunal a serious error of professional judgment, an error which might well not have been made had he not been under the influence of alcohol.

The Tribunal did not find that the doctor failed to make a proper examination of the infant. Nevertheless all the members of the Tribunal took "an extremely grave and serious view of the conduct and behaviour of the doctor" on the night in question. However, the Tribunal considered that all these facts amounted only to a single incident and came to the conclusion that it was not justified in saying that this single incident was such as to cause the inclusion of the respondent in the Medical List to be prejudicial to the efficiency of the General Medical Services. The Tribunal was further of the opinion that "in all probability no treatment, whatever it might have been, would if administered at the time at which the respondent arrived at the house (or possibly even three or four hours earlier) have saved the life of the child" and that "no negligence of the respondent in any way caused or contributed to the death of the child."

The Tribunal made no order as to the costs of the parties to the inquiry.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

Thomas Shirley Hele, M.D., F.R.C.P., Master of Emmanuel College, has been reappointed a Deputy Vice-chancellor of the University for the year 1949–50.

UNIVERSITY OF LONDON

A course of six lectures in physiology will be delivered by Dr. Bernhard Katz at University College, Gower Street, London, W.C., on Fridays, October 21 and 28 and November 4, 11, 18, and 25, at 5.15 p.m. His subject is "Transmission of Excitation in Nerve and Muscle."

Dr. Charity Waymouth will deliver two lectures on "Technique and Applications of Tissue Culture" at University College on Mondays, October 24 and 31, at 4.45 p.m.

A course of four lectures on "Bacterial Toxins" will be delivered by Dr. W. E. Van Heyningen at University College on Mondays, November 7, 14, 21, and 28, at 4.45 p.m.

On Monday, December 5, at 5.30 p.m., Dr. G. L. Brown, Jodrell Professor of Physiology in the University, will deliver his inaugural lecture at University College.

Professor V. du Vigneaud, of Cornell University Medical College, will deliver a course of three lectures on "The Indispensability of Biologically Labile Methyl Groups in the Diet and Transmethylation" in the Meyerstein Lecture Theatre, Westminster Medical School, Horseferry Road, London, S.W., on October 28 and 31 and November 2, at 5.30 p.m.

Admission to all the above lectures is free, without ticket.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended September 24. [No. 38

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† *Deaths from measles and scarlet fever for England and Wales, London* (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

‖ Includes puerperal fever for England and Wales and Eire.

EPIDEMIOLOGICAL NOTES

Poliomyelitis

The total number of notifications in England and Wales in the week ended October 1 was: poliomyelitis 331 (268), polio encephalitis 26 (27). The figures for the previous week are shown in parentheses. These are the highest figures this year. In 1947 figures for the corresponding week were poliomyelitis 441, polio-encephalitis 32.

Multiple cases (poliomyelitis and polio-encephalitis together) were reported from the following counties: London 44 (48), Bedford 5 (1), Berkshire 5 (3), Buckingham 2 (1), Chester 4 (7), Cornwall 8 (8), Dorset 5 (4), Durham 3 (1), Essex 26 (17), *Gloucester 17 (0), Hertford 12 (7), Kent 19 (18), Lancaster 4* (24), Leicester 2 (5), Norfolk 4 (2), Northampton 4 (4), Northumberland 6 (13), Nottingham 9 (9), Somerset 6 (7), Southampton 7 (8), East Suffolk 2 (5), Surrey 9 (11), East Sussex 5 (1), Warwick 13 (8), Wiltshire 8 (9), East Yorks 3 (1), North Yorks 2 (1), West Yorks 38 (19), Glamorgan 6 (3), Monmouth 2 (0).

Discussion of Table

In *England and Wales* decreases were recorded in the notifications of whooping-cough 119 and acute poliomyelitis 43. There were increases in the incidence of scarlet fever 155 and diphtheria 14.

The local trends of scarlet fever showed only small variations from the preceding week except in Yorkshire West Riding where there was an increase of 55. Notifications of diphtheria have almost been doubled in the past month; the chief feature of the returns was a rise of 17 in Lancashire (14 of the 21 cases in this county were notified in Liverpool C.B.).

There were only small variations in the local trends of measles, the largest being an increase of 27 in Lancashire. The largest fluctuations in the notifications of whooping-cough were decreases in Middlesex 29 and Essex 30.

In Durham, Hetton U.D., where 15 cases were reported in the preceding week, 17 further cases of dysentery were notified. Other large returns for dysentery were London 16, Lancashire 16 (Liverpool C.B. 10), Glamorganshire 8 (Cardiff C.B. 6). Outbreaks of food-poisoning were notified in Yorkshire West Riding 55 (Batley M.B. 32, Sheffield C.B. 20); Essex 5 (Southend-on-Sea C.B. 19); and London 34.

In *Scotland* there were increases in the notifications of scarlet fever 33, acute primary pneumonia 33, and dysentery 22, with decreases in the incidence of whooping-cough 28 and measles 22. The rise in the notifications of scarlet fever occurred in the western area. Of the 76 cases of dysentery 60 were notified in Glasgow.

In *Eire* the notifications of measles were 23 fewer than in the preceding week, while increases were reported for scarlet fever 11 and whooping-cough 10. The incidence of diarrhoea and enteritis remained high at 136 for the whole country; of these, 101 were notified in Dublin C.B. The rise in the notifications of scarlet fever and whooping-cough was contributed by Dublin C.B.

In *Northern Ireland* decreases were reported in the notifications of measles 10 and whooping-cough 11. The incidence of scarlet fever remained at the high level of the preceding week.

Week Ending October 1

Notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,305, whooping-cough 956, diphtheria 76, measles 780, acute pneumonia 313, cerebrospinal fever 25, acute poliomyelitis 331, acute polio-encephalitis 26, dysentery 163, paratyphoid fever 24, typhoid fever 12, food-poisoning 553.

The council of Dr. Barnardo's Homes announces that the Watts Naval Training School at Elmham, Norfolk, and the Russell-Cotes Nautical School at Parkstone, Dorset, are to be amalgamated as one establishment under the new title of the Parkstone Sea Training School. As a consequence of this change the Watts School will cease to function as a sea-training centre and will for the time being become a branch home for boys.

Medical News

Appointments to Royal Households

Dr. J. N. Loring has been appointed Apothecary to His Majesty's Medical Household in the room of Sir Frederick Stanley Hewett, who has been appointed Extra Surgeon Apothecary to His Majesty's and to Queen Mary's Medical Households. Dr. Loring has also been appointed Apothecary to Queen Mary's Medical Household and to the Household of Princess Elizabeth and the Duke of Edinburgh. Sir James Walton has been appointed an Extra Surgeon and Mr. Guy Capper Birt an Extra Surgeon Dentist to Her Majesty Queen Mary's Medical Household. All the appointments date from October 1.

Unesco Book Coupons

Individuals and institutions in "soft currency" countries may obtain book coupons to facilitate buying books or periodicals from the U.S.A., Switzerland, Czechoslovakia, India, and France. The coupons have a dollar face value, and may be bought with sterling from Unesco Book Coupons, Book Tokens Limited, 28, Little Russell Street, London, W.C.1. Further particulars may be obtained from the same address.

Gold Medal

The South Wales Institute of Engineers has awarded Dr. T. H. Jenkins the Institute Gold Medal for 1948 for his paper "Medico-mining Aspects of Pneumoconiosis in South Wales." Dr. Jenkins is divisional medical officer for the South-Western Division of the National Coal Board. While working as a collier in the Garw Valley he matriculated in 1924 and entered the University College of South Wales. He obtained his B.Sc. in mining, and subsequently studied medicine at University College Hospital, London, where he took the conjoint diploma and London degree in 1938.

Sir Sydney Smith

The honorary degree of M.D. of the University of Louvain was conferred upon Sir Sydney Smith, Regius Professor of Forensic Medicine and Dean of the Faculty of Medicine in the University of Edinburgh, at Louvain on October 10.

A New Journal

The Institute of Laryngology and Otology, Royal National Throat, Nose and Ear Hospital, has commenced publication of a new journal, *Annals of the Institute of Laryngology and Otology*. The *Annals* will publish reports of the work of the hospital, and contributions are invited from past and present members of the Institute. Based as they are on the largest hospital in Britain devoted solely to otorhinolaryngology, the *Annals* are an important addition to medical literature. They will appear half-yearly, price 5s. per issue, and are published from 330, Gray's Inn Road, London, W.C.1.

The American Heart Association's Journal

The American Heart Association is to begin publishing in January a new official monthly journal entitled *Circulation—The Journal of the American Heart Association*. With the new publication the American Heart Association will terminate sponsorship of the monthly *American Heart Journal* with the December, 1949, number. According to the announcement issued by the American Heart Association, "The needs of the members of the American Heart Association and of the medical profession in general require a larger official journal to keep pace with advances in the field of cardiovascular diseases. *Circulation* will be published in a larger format . . . which will assure accelerated publication of articles, bringing valuable medical material to the professional reader at the earliest possible opportunity." Dr. Thomas M. McMillan, for some years editor-in-chief of the *American Heart Journal*, will continue in that capacity for *Circulation*, and it is expected that the associate editors and editorial board of the older publication will also serve in the same capacities on the new magazine. The publishers will be Grune and Stratton, Inc., 381, Fourth Avenue, New York, 16.

Invested with G.C.V.O.

The King invested Sir Maurice Cassidy with the insignia of the G.C.V.O. at his home on October 10. Sir Maurice Cassidy was unable to go to Buckingham Palace to receive the honour, which, as reported previously, was gazetted in May, because of the injuries that he received in a car accident six months ago.

Photographic Exhibition

The Royal Photographic Society's annual exhibition at 16, Princes Gate, London, S.W.7, includes a number of photographs of interest to medical men. The illustrations of the pathological specimens of heart and kidney showed the remarkable clarity that photography can attain in skilled hands. Much depends on adept lighting of the object, as was shown particularly clearly in five photographs of a man with exophthalmic ophthalmoplegia directing his eyes to show the effects of the disorder. These photographs are of a quality that deserves study by anyone wanting to illustrate an article or a textbook. The exhibition remains open until October 26.

Periodicals at Special Rates

The Times has announced that full-time students may now buy it for 2d. Inquirers should write to the Manager, Subscription Department, *The Times*, Printing House Square, London, E.C.4. The weekly journal, the *Spectator*, is now obtainable by members of the medical profession for the special subscription of £1 1s. instead of 30s. a year. Particulars may be obtained from the *Spectator*, 99, Gower Street, London, W.C.1.

Tuberculosis as Industrial Disease

The Industrial Diseases Subcommittee of the Industrial Injuries Advisory Council is considering whether tuberculosis should be a "prescribed disease" under the National Insurance (Industrial Injuries) Act for nurses and other classes of health workers. "Prescribing" a disease in relation to any particular class of person makes the benefits provided under the Industrial Injuries Act available to people in that class if they are employed under a contract of service and develop the disease as a result of their employment. Industrial injury benefits are appreciably greater than those obtained under the National Insurance Act. Persons and organizations are invited to submit written evidence as soon as possible, and in any case before December 1, to Mr. F. K. Forrester, Ministry of National Insurance, 6, Curzon Street, London, W.1, who will supply further information on request.

B.C.G. from Denmark

The first consignment of B.C.G. to be imported under the Ministry of Health's scheme arrived in England by air from Copenhagen on October 3, and was sent to the Public Health Laboratory at Colindale. Part of the consignment, which contained 30 ml. of the vaccine, is to be used at the Children's Hospital at Sheffield, where some of the staff have volunteered to be vaccinated. The arrangements for trying out B.C.G. in this country were described in the *Journal* of July 2 (p. 29).

Child Health Lectures in Czechoslovakia

Professor J. C. Spence, Professor of Child Health in the University of Durham, is now in Czechoslovakia lecturing for the British Council. The Czech Ministry of Health, the Czech Paediatric Society, the Czechoslovak-British Medical Society, and the Institute of Social Medicine, Charles University, have co-operated in arranging the tour.

Wills

Dr. Alan Leonard Smith Tuke, of Dunfermline, left £65,246; Dr. George Ezra Halstead, of Bideford, £22,394; Dr. Alexander McConnell Erskine, of Goole, £18,477; and Dr. Percy Kitchin, formerly of Bournemouth, £46,847.

COMING EVENTS

Royal Medical Society

The 1949–50 session of the Royal Medical Society of Edinburgh (7, Melbourne Place, Edinburgh) opens to-day (Friday, October 14) at 8 p.m., when Professor A. Murray Drennan delivers the inaugural address entitled "Whither Are We Going?" Further meetings will be held on Fridays at 8 p.m., as follows: October 21, Mr. K. Wood, "Clubbing of the Fingers"; October 28, Sir Philip Manson-Bahr, "The Dawn of Tropical Medicine (The Life and Work of Sir Patrick Manson)"; November 4, Mr. C. W. Mercer, "The Aetiology and Treatment of Ulcerative Colitis"; November 11, Mr. R. C. Tyldesley, "Unorthodox Healing—An Assessment"; November 25, Mr. A. H. Duncan, "The Aetiology of Neoplasia"; December 2, Mr. J. J. MacCabe, "Disseminated Sclerosis"; December 9, symposium on "Pyrexia"; January 13, dissertation by Mr. I. B. Tait; January 20, Mr. D. W. MacLean, "The Handicapped Child"; January 27, Sir Hugh Cairns, "Head Injuries"; February 3, Mr. J. B. McWhinnie, "Physique, Diathesis, and Temperament"; February 10, dissertation by Mr. L. R. Roberts; February 17, Professor Walter Mercer, "Manipulative Surgery"; February 24, Mr. A. Fraser Darling, "The Nature of Cutaneous Sensation"; March 3, Sir Edward Mellanby, F.R.S., "Widespread Nerve Degeneration due to Abnormal Bone Growth—An Experimental Investigation"; March 10, valedictory address by the senior president. The presidents' annual dinner will be held at the Royal College of Physicians of Edinburgh, Queen Street, Edinburgh, on Thursday, November 17, at 7.15 for 7.30 p.m., when Sir Alexander Fleming, F.R.S., will be the guest of honour. The annual extraordinary general meeting of the society will be held on Wednesday, March 15, at 7 p.m.

Hunterian Society

The programme of the Hunterian Society for the 1949–50 session is as follows: October 17, 7 for 7.30 p.m., dinner-meeting at Talbot Restaurant, 64, London Wall, E.C., presidential address by Dr. William Thomson Brown on "Balance"; November 21, 8.30 p.m., at Society of Apothecaries of London, Black Friars Lane, Queen Victoria Street, E.C., discussion, "That Alcohol has Contributed more to the Happiness than to the Misery of Mankind," proposed by Dr. John Y. Dent and Dr. Desmond Curran and opposed by Dr. Henry Yellowlees and Mr. Archibald Crawford, K.C.; December 5, 7 for 7.30 p.m., dinner-meeting at Talbot Restaurant, discussion, "The Assessment of Surgical Risk," to be opened by Sir Horace Evans, Dr. Frankis T. Evans, and Mr. A. Lawrence Abel; January 16, 8.30 p.m., at Mansion House, London, E.C., Hunterian Lecture by Professor René-A. Gutmann (Paris), "The Early Diagnosis of Gastric Carcinoma"; February 16, at Grosvenor House, Park Lane, London, W., annual dinner; February 27, 8.30 p.m., at Mansion House, Hunterian Oration by Dr. Daniel T. Davies, "John Hunter, the Man and his Message"; March 20, 7 for 7.30 p.m., dinner-meeting at Talbot Restaurant, discussion, "Modern Trends in the Diagnosis and Treatment of Pulmonary Tuberculosis," to be opened by Dr. Geoffrey Marshall and Mr. T. Holmes Sellors; April 17, 7 for 7.30 p.m., annual general dinner-meeting at Talbot Restaurant, followed by a demonstration of hypnotism by Mr. Peter Casson.

Edinburgh Lectures

In connexion with the postgraduate courses in medicine and surgery the Edinburgh Postgraduate Board for Medicine has arranged a series of open lectures on subjects of wide biological interest to be given on Tuesdays, at 5 p.m., during the winter term in the Anatomy Lecture Theatre, Edinburgh University New Buildings, beginning on October 25. All students and graduates are invited to attend. Details will be published under "Societies and Lectures" in the *Journal*.

Forensic Medicine Congress

The Third Congress of the International Academy of Forensic and Social Medicine will be held in Cairo on March 21–26, 1950.

Institute of Diseases of the Chest

A ceremony to mark the opening of the new premises of the Institute of Diseases of the Chest (British Postgraduate Medical Federation) in the grounds of Brompton Hospital, Fulham Road, London, S.W., will be held on Wednesday, October 26, at 3 p.m., when inaugural addresses will be delivered by Sir John Anderson, chairman of the Governing Body of the Federation, Sir Francis Fraser, director of the Federation, Sir Robert A. Young, chairman of the Board of Governors of the Hospitals for Diseases of the Chest and consulting physician to Brompton Hospital, and Dr. S. Roodhouse Gloyne, consulting pathologist to the London Chest Hospital.

London Hospital Old Students' Dinner

The London Hospital Old Students' Dinner will be held at the Trocadero Restaurant, Piccadilly Circus, London, W., on Thursday, October 27. Tickets, price £1 1s., can be obtained from Dr. R. R. Bomford, 6, Devonshire Place, London, W.1.

SOCIETIES AND LECTURES

Friday

Royal Medical Society, 7, Melbourne Place, Edinburgh.—*October 14, 8 p.m., "Whither Are We Going?"* Inaugural address by Professor A. Murray Drennan.

Monday

Hunterian Society.—At Talbot Restaurant, 64, London Wall, E.C., October 17, 7 for 7.30 p.m., dinner-meeting; *"Balance,"* Presidential address by Dr. William Thomson Brown.

Institute of Laryngology and Otology, 330–332, Gray's Inn Road, London, W.C.—October 17, 2.30 p.m., *"Tumours of the Post-nasal Space,"* by Mr. F. C. W. Capps.

London University.—At University College, Gower Street, London, W.C., October 17, 5.15 p.m., *"The Structure of Peripheral Nerve,"* by Professor J. Z. Young.

Tuesday

Institute of Laryngology and Otology, 330–332, Gray's Inn Road, London, W.C.—October 18, 2.30 p.m., *"Malignant Diseases and Radiotherapy,"* by Mr. W. A. Mill.

Royal College of Physicians of London, Pall Mall East, S.W.—October 18, 3 p.m., *"Individuality in Medicine,"* Harveian Oration by Dr. Geoffrey Marshall.

Society for the Study of Addiction.—At Medical Society of London, 11, Chandos Street, Cavendish Square, W., October 18, 4 p.m., *"The Problems for Research in the Study of Addiction,"* Presidential address by Professor F. L. Golla. A discussion will follow.

Wednesday

Glasgow University: Department of Ophthalmology.—*October 19, 8 p.m., "Tobacco Amblyopia,"* by Dr. R. Leishman.

Harveian Society of London.—At King's College Hospital Medical School, Denmark Hill, S.E., October 19, 4.15 p.m., Clinical meeting.

London University.—At University College (Anatomy Theatre), Gower Street, W.C., October 19, 5.30 p.m., *"Growth and Reproduction of Bacteria,"* by Sir Paul Fildes, F.R.S.

North-East Metropolitan Regional Tuberculosis Society.—October 19, 2.30 p.m., visit to Ware Park Sanatorium, Herts *"Resection of the Lung for Pulmonary Tuberculosis,"* by Mr. O. S Tubbs.

Royal Institute of Public Health and Hygiene, 28, Portland Place, London, W.—October 19, 3.30 p.m., *"The Present Position of Diphtheria Immunization,"* by Dr. W. W. King-Brown.

Society of Radiographers.—At Royal College of Nursing (Cowdray Hall), 1A, Henrietta Place, Cavendish Square, London, W., October 19, 6.30 p.m., *"The Radiography of Infants and Children,"* Stanley Melville Memorial Lecture by Dr. C. G. Teall

Thursday

British Institute of Radiology, 32, Welbeck Street, London, W.—October 20, 8.15 p.m., discussion: *"Instrumental Aids to Diagnostic Techniques."* Speakers: Dr. T. H. Hills, Mr. R. W. Stanford, Dr. G. R. Airth, and Mr. E. D. Ormerod.

Edinburgh Clinical Club.—In B.M.A. Rooms, 7, Drumsheugh Gardens, Edinburgh, October 20, 8 p.m., opening meeting of club, *"Discussion on the Problems of Married Life,"* by Reverend W. S Tindal and Dr. W. P. Kraemer.

Institute of Urology.—At Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C., October 20, 5 p.m., *"The Conservative Treatment of Hydronephrosis,"* by Professor V. W. Dix.

London University.—At University College (Anatomy Theatre), Gower Street, W.C., October 20, 5.30 p.m., *"Growth and Reproduction of Bacteria,"* by Sir Paul Fildes, F.R.S.

Royal Society of Tropical Medicine and Hygiene, 26, Portland Place, London, W.—October 20, 7.30 p.m., *"Tropical Medicine as a Career,"* Presidential address by Professor H. E. Shortt.

St. George's Hospital Medical School, Hyde Park Corner, London, S.W.—October 20, 4.30 p.m., lecture-demonstration: *"Neurology,"* by Dr. D. J. Williams.

Friday

FACULTY OF RADIOLOGISTS.—At Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C., October 21, 2.15 p.m., Diagnosis Section meeting, "*The Value of Tannic Acid Barium Enema in Colonic Investigation*," by Dr. J. H. L. Conway-Hughes; "*The Causes of Failure After Gastrectomy for Peptic Ulcer*," by Dr. C. N. Pulvertaft; "*The X-ray Appearances of Acquired Collapse (Atelectasis) of the Upper Lobes*," by Dr. G. Simon.

INSTITUTE OF PHYSICS: INDUSTRIAL SPECTROSCOPY GROUP.—At 47, Belgrave Square, London, S.W., October 21, 4 p.m., annual general meeting; "*Physical Methods in the Forensic Laboratory*," by Dr. F. G. Tryhorn.

LONDON UNIVERSITY.—At University College, Gower Street, London, W.C., October 21, 5.15 p.m., "*Transmission of Excitation in Nerve and Muscle*," by Dr. Bernhard Katz.

LONDON UNIVERSITY.—At University College (Anatomy Theatre), Gower Street, W.C., October 21, 5.30 p.m., "*Growth and Reproduction of Bacteria*," by Sir Paul Fildes, F.R.S.

ROYAL INSTITUTE OF PHILOSOPHY, 14, Gordon Square, London, W.C.—October 21, 5.15 p.m., "*Russell's Theory of the External World*," by Professor H. H. Price.

ROYAL MEDICAL SOCIETY, 7, Melbourne Place, Edinburgh.—October 21, 8 p.m., "*Clubbing of the Fingers*," by Mr. K. Wood.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—At South Kensington Hotel, 41, Queen's Gate Terrace, London, S.W., October 21, 7.15 p.m. for 7.30 p.m., dinner; 8.30 p.m., "*The Dramatic in Gynaecology and Obstetrics*," Presidential address by Mr. V. B. Green-Armytage.

Saturday

BIOCHEMICAL SOCIETY.—At Biochemistry Department, King's College, Strand, London, W.C., October 22, 2 p.m., 280th meeting.

APPOINTMENTS

Dr. Herbert Kent, formerly Fellow in Physical Medicine and Rehabilitation of the New York University, Bellevue Medical Center, and National Foundation for Infantile Paralysis, has been appointed Chief of Physical Medicine Rehabilitation at the Veterans Administration Hospital, Indianapolis.

The Secretary of State for Scotland has appointed Dr. Catherine Haldane Stobie Begg to be a Deputy Commissioner of the General Board of Control for Scotland.

Dr. Begg graduated M.B., Ch.B at Glasgow University in 1932 and has held appointments in Glasgow Royal and Western Infirmaries, Glasgow Southern General Hospital, and various mental hospitals She is at present Senior Medical Officer at Stoneyetts Mental Hospital, Glasgow.

CENTRAL COUNCIL FOR HEALTH EDUCATION.—The following appointments have been announced: *Deputy to the Medical Adviser and Secretary*, L. J. H. Burton, M.R.C.S., L.R.C.P., D.P.H. *Assistant*, Anne F. Burgess, M.B., Ch.B., L.D.S.

NELSON, IVAN D. M., M.B., Ch.B., D.P.H., Deputy Medical Officer of Health, County Borough of Dewsbury.

RAFTERY, LILIAN, M.R.C.S., L.R.C.P., M.M.S.A., M.R.C.O.G., Assistant Visiting Gynaecologist and Obstetrician, King Edward VIII Hospital, Durban, South Africa.

RUNWELL HOSPITAL, near Wickford, Essex.—*Clinical Research Fellow*, P. Macdonald Tow, M.B., B.S. *Senior Registrar*, M. G. Valentine, M.D., D.P.M.

STEWART, R. H. M., M.D., Assistant Senior Medical Officer, Manchester Regional Hospital Board.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Black.—On October 2, 1949 at Dunfermline, to Hilda (née Murray), wife of J. Murray Black, F.R.C.S.Ed., a daughter.

Ferguson.—On September 6, 1949, at Douglas, Isle of Man, to Frances (née Wright), wife of Dr. J. H. Ferguson, a brother for Frances, Elizabeth, and Robert—George Wright.

Mills.—On October 6, 1949, to Margaret Jane, M.B., D.A., wife of Wilfrid Mills, F.R.C.S., a son.

MARRIAGES

Binns—Whitaker.—On September 17, 1949, at Ewell, Surrey, Surgeon Lieutenant-Commander George Augustus Binns, R.N., of Leicester, to Joan Whitaker, of Ewell.

DEATHS

Aspinwall.—On October 2, 1949, at Heswall, Cheshire, Joan Fullerton Aspinwall, M.R.C.S., L.R.C.P., aged 85.

Bentley.—On September 26, 1949, Harold Bentley, M.R.C.S., L.R.C.P., late of Mitcham, Surrey.

Ford.—On October 3, 1949, at 2, Derwent Road, Eastbourne, Frank Chubb Ford, M.R.C.S., L.R.C.P., late of Wimbledon and Rotherfield, aged 82.

Freeman.—On September 29, 1949, Harry Freeman, F.R.C.S., M.M.S.A., of 69, Harley House, London, N.W.

Greenwood.—On October 5, 1949, in London, Major Greenwood, D.Sc., F.R.C.P., F.R.S., of Hillcrest, 102, Church Hill, Loughton, Essex, aged 69.

Hoffman.—On September 26, 1949, at his home, The Red House, Cranham, Gloucester, Geoffrey Arthur Hoffman, B.A., M.B., T.C.Dub.

Johns.—On September 27, 1949, at the Old Mill House, Adderbury, Oxon, Archibald Tisdall Johns, M.D., aged 77.

Mathews.—On September 24, 1949, at Wayside, Gossamer Lane, Aldwick, Bognor Regis, Sussex, William L'Estrange Mathews, M.R.C.S., L.R.C.P.

Prentice.—On September 19, 1949, in hospital, John Stuart Prentice, M.B., Ch.B.

Williams.—On September 21, 1949, Geoffrey Commeline Williams, O.B.E., M.R.C.S., L.R.C.P., D.P.H., of 8, Belbroughton Road, Oxford.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Trachoma

Q.—*What is the cause of trachoma? How useful are the sulphonamides and antibiotics in the treatment of this condition? Where are the best articles to be found concerning the disease in all its aspects?*

A.—*It is now generally agreed that trachoma is due to a virus infection, the virus being one of the large-sized variety.* The mode of transmission—for example, the question whether the virus is louse-borne—is still in dispute. As with the other infections due to large-size viruses, the sulphonamides have proved of great value. The place of penicillin in the treatment of trachoma is still uncertain. When the sulphonamides are used it is advisable to eradicate secondary infection by a course of sulphonamide systemically. The trachoma itself appears to be readily amenable to local sulphonamide therapy, which may have to be continued for several months. Daily painting with 30% sodium sulphacetamide, and the use of an ointment of 6% of the same drug three or four times a day, give good results. It is advisable to eradicate as much of the infective material as possible by mechanical means such as expression before starting on local therapy. In old-standing cases eradicating a virus infection does not, of course, overcome mechanical distortion of the lid from shrinkage of tissue.

The best account of modern teaching is the *Aetiology of Trachoma* by L. A. Julianelle (Oxford University Press, 1938). *Trachoma*, by A. F. MacCallan (London, Butterworth & Co., 1936), is also useful, especially for the older teaching. An account of the use of sulphonamides in trachoma is contained in a paper on the treatment of trachoma by Arnold Sorsby in the *British Journal of Ophthalmology* (1945, 29, 98).

Hyoscine for Sea-sickness

Q.—*A family consisting of the parents and two children, aged 4 and 2, are travelling to South Africa. What would be the appropriate dose of hyoscine in each case? Should it be started before embarkation? How long should it be continued, and are there any side-effects?*

A.—Presumably the hyoscine is intended to prevent sea-sickness. If so, an adult should take a daily dose of 1/100 gr. (0.65 mg.) of hyoscine hydrobromide. One dose daily is enough, taken in the morning. A child of 4 should take one-fifth of this dose, and a child of 2 one-tenth. There is no need to start taking the drug before embarkation. It can be continued throughout the voyage. The only reaction is some dryness of the mouth.

Prostatectomy and Sexual Potency

Q.—*What is now considered the most satisfactory surgical approach in prostatectomy? What is the effect of the operation on the sexual life of an otherwise healthy male of middle age, particularly in relation to potency and libido, power of erection, emission and ejaculation, orgasm, spermatogenesis, and ability to procreate?*

A.—Potency and libido are not usually affected by prostatectomy in a healthy middle-aged male. Many of the patients undergoing prostatectomy have already ceased to have coitus, but Thomson-Walker found that, among males of all ages, no difference was observed in sexual power in 67%; 20% suffered subsequently from a gradual loss of vigour: and 13% became impotent. Ejaculation does not usually occur after enucleation of the prostate, the semen passing back into the bladder and being voided in the next specimen of urine. In spite of this the patient has an orgasm. It is usually said that sterility follows prostatectomy, but the writer has known two or three

cases in which the wife has conceived after her husband has been subjected to prostatectomy. If it were not for the fact that the wives of most men undergoing prostatectomy are themselves past child-bearing age, such cases would probably be more numerous. It must be remembered, however, that many surgeons divide the vasa in order to reduce the incidence of post-operative epididymitis, and that this leads to sterility.

It cannot be said that any one technique of prostatectomy is recognized as being superior to all others. What form of operation is carried out will depend on the state of the patient and on the surgeon's personal opinion. Retropubic prostatectomy and the Harris technique are both excellent operations for certain patients, but they should not be used as routine measures.

Coronary Thrombosis and Air Travel

Q.—*Are there any objections to air travel for patients with a history of coronary thrombosis some years ago?*

A.—Provided oxygen is used for flight above 10,000 feet (3,000 metres) there should be no greater risk to a subject well recovered from a coronary thrombosis in this mode of travel than in any other, and fatigue is likely to be considerably less.

Thrombophlebitis Migrans

Q.—*What is the treatment for repeated attacks of thrombophlebitis over a period of 18 months involving the superficial veins of arms and legs in a woman of 48? The erythrocyte sedimentation rate is 11 mm. in one hour, and the blood pressure 146/90 mm. Hg. She has no infected teeth or gall-bladder infection. Section of an infected vein has shown well-organized thrombus. Sulphonamides, large doses of vitamins, and the usual treatment for phlebitis have been unsuccessful. What further treatment could be tried, and what is the prognosis?*

A.—This patient seems to be suffering from thrombophlebitis migrans, although the usual associated pyrexia and low blood pressure seem to be absent. Dicoumarol is very useful in this rebellious complaint, and should be administered so as to keep the prothrombin time double the normal and persisted in for three to six months. The condition is as a rule not disabling, and the patient should, if possible, be ambulatory; this can be attained by supporting the legs with elastic bandages. A long holiday in a warm place is often beneficial. The disease is not usually dangerous and burns itself out in time, but rarely it may progress to a malignant thrombophilia in which the largest vessels may become involved and even arteries be blocked, with consequent cardiac damage or loss of limbs.

Quinine Test of Liver Function

Q.—*I have seen a reference to an article by Pallardo on the quinine test for liver function, for which he claimed good results. I should be grateful for details of procedure, the field of application, interpretation of results, and relative merits compared with other liver function tests.*

A.—The quinine test for liver function was described by Pallardo in 1947 (*Sem. méd.*, **54**, 721), and depends on the detection of quinine in the urine after oral administration of the drug. Quinine sulphate 0.2 to 0.25 g. is given to the fasting patient. The urine is collected at 30 minutes, two hours, and 12 hours afterwards. The three specimens of urine are tested for quinine with the Tanret reagent, which is prepared as follows. Dissolve 1.35 g. of mercuric chloride in 25 ml. of water, add to this solution 3.32 g. of potassium iodide dissolved in 25 ml. of water, then make the total solution up to 60 ml. with distilled water and add 20 ml. of glacial acetic acid to the mixture. After the Tanret reagent is added a positive reaction is indicated by the development of turbidity. Normal subjects give negative reactions under these conditions.

The test is positive in the urine from a high proportion of cases of liver damage, irrespective of the cause, although occasional negative findings are also recorded in conditions such as cirrhosis and infective hepatitis. The test may also be positive in cholecystitis and hepatic carcinomatosis, which would appear to limit its value in differential diagnosis. The author claims that it is a sensitive index of liver damage.

NOTES AND COMMENTS

Enlarged Liver after Amoebic Dysentery.—Dr. C. F. J. Cropper (Ronkswood, Worcester) writes: I should like to submit some comments on the answer to the query entitled "Enlarged Liver after Amoebic Dysentery" ("Any Questions?" August 20, p. 448). It appears to me that the writer was presented with a common, and in this case simple, problem to which he himself provided the solution by his demonstration of the regression of an enlarged liver beginning during the course of emetine injections. The history of amoebic dysentery and the response to this infallible therapeutic test can surely leave little doubt about the diagnosis. Incidentally, in general experience leucocytosis is frequently absent in amoebic hepatitis. There is no mention, either in the query or in the reply, of sigmoidoscopy. It is disturbing to find so essential a diagnostic procedure ignored in this way. If this neglect of sigmoidoscopy is widespread, innumerable cases of amoebiasis originating in both world wars are certainly being missed. (I use the word "both" advisedly, since more than one case has come to light in this hospital which has remained undiagnosed and untreated from the 1914–18 war: these have been diagnosed purely on sigmoidoscopy appearances.) Whilst in no way belittling the significance of stool tests, it needs to be stressed that only the select few with long apprenticeship can identify cysts with competence, and in any case the chronic patient so often yields negative results. Hand in hand with microscopy should go sigmoidoscopy, the technique and interpretation of which can readily be taught. This strangely neglected instrument frequently gives in a few moments a certain answer in the search for amoebiasis. Physicians handling cases potentially infected with this disease should have indelibly printed on their minds the picture of the tiny wart-like projections, aptly likened to colonies of pneumococci on blood-agar, which are the commonest lesions of chronic amoebic dysentery (*Lancet*, 1945, 2, 460). In the tropical section of this hospital, in the first six months of this year no less than nineteen cases with negative stools but with dysenteric symptoms were revealed by the finding of these "pin-point craters." In the great majority of cases both symptoms and lesions cleared up with anti-amoebic treatment. There is, in my opinion, no answer to the problem of amoebiasis in this and many other countries except the adoption of sigmoidoscopy as a simple out-patient procedure.

Wax in the Ears.—Mr. F. K. Hayman (Sharnbrook, Bedford) writes: Your correspondent ("Any Questions?" October 1, p. 767) asks about any prophylaxis against wax in the ears. I have found that a good deal of so-called wax is composed of bits of hair, dandruff, ordinary dust, etc., bound together by soap—shaving or toilet—insufficiently rinsed off, and probably pushed in by the towel. I have often found a soapy turbidity in the water used for syringing, and have cautioned such patients not to allow soap to enter the meatus if possible, and in any case to rinse about the ears very thoroughly.

Dichloracetylene Poisoning.—Dr. C. F. Scurr (London, S.W.) writes: Your answer upon this subject ("Any Questions?" September 24, p. 717) is incomplete. Had the question been referred to an anaesthetist instead of an industrial toxicologist a more adequate answer would have been given. Dichloracetylene is a product of the decomposition of trichlorethylene with alkali under certain conditions—e.g., by soda lime in a closed-circuit anaesthetic apparatus. A detailed account of the toxic effects and necropsy findings is given by Humphrey and McClelland (*British Medical Journal*, 1944, **1**, 315) and by Carden (ibid., 1944, **1**, 319).

Correction

Dr. Sidney G. Hamilton (Woolacombe, N. Devon) writes that in his letter on "Antihistamine Drugs in General Practice" ("Points from Letters," October 1, p. 760) the words "phenacetin and codeine compound" in the seventh line from the end of the paragraph should read "pyranisamine maleate."

All communications with regard to editorial business should be addressed to The Editor, British Medical Journal, B.M.A. House, Tavistock Square, London, W.C.1. Telephone: Euston 2111. Telegrams: *Alitiology, Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). Telephone: Euston 2111. Telegrams: *Britmedads, Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. Telephone: Euston 2111. Telegrams: *Medisecra, Westcent, London.*

B.M.A. Scottish Office: 7, Drumsheugh Gardens, Edinburgh.

SUPPLEMENT TO THE
BRITISH MEDICAL JOURNAL
LONDON SATURDAY OCTOBER 15 1949

THE SECRETARY REPORTS

THE MINISTER'S PRESS CONFERENCE

Nothing startling or novel came out of the Minister's Press Conference, reported on another page. On the subject of general practitioner remuneration it is useful to have had the Minister's assurance, in regard to the Ministry's survey of incomes, that he "would like to have the facts agreed with the profession," although he added his own impression that the evidence showed "that Spens has been more than honoured." The Minister made some other points which were interesting and have been noted. Some who were present at the Conference remarked afterwards on the pains the Minister was at to distinguish between the Health Service and the National Insurance Scheme. He spoke about "misunderstandings," and said that "many people still assume that the National Health Service is financed by the weekly contributions to National Insurance." This led to abuse through people being determined "to have their money's worth." He appealed to the Press to disabuse the public of these erroneous beliefs. The B.M.A. foresaw that this might happen and has been stressing the point for over a year. The same to a lesser extent is true of the Minister's appeals to the public to use the Service with restraint. It is true that he has made such appeals from time to time, but they have been so closely associated by a section of the Press with glowing advertisements of the "free" benefits to be obtained under the scheme that it is small wonder that less attention has been paid to them than might have been expected. Once again the B.M.A., at some cost to itself both in money and unpopularity (which these days seem to attach to anyone suggesting a damper on public extravagance), took the initiative.

What are the facts? So far back as May, 1948, the B.M.A. Public Relations Department was issuing leaflets for distribution to the public which *inter alia* pointed out that only 10d. out of the male worker's weekly contribution of 4s. 11d. would go to the Health Service, adding that ten-elevenths of the total money paid in respect of any one worker would go to the cash benefits of insurance. Two months later the Association issued an illustrated folder, "The New Health Service and You." Of this leaflet, copies of which were sent direct from B.M.A. House to all doctors who applied for them, 250,000 were printed and distributed in August, and in September a further 300,000 were printed. By the end of October altogether nearly half a million copies had been asked for and distributed. This folder pointed out that the public as well as doctors, other professional people in the Service, and the Government had "a part to play in making the Service a success," adding that "if there is 'a run' on the surgery just because the Service is 'free-at-the-time,' doctors will be unable to give as much attention to each patient as they would wish. No one can give his best if he is overworked."

In the same month posters were prepared and issued for display in surgeries, executive council offices, and elsewhere appealing to the public to help the doctor to make the best use of his time by sending in requests for home visits early in the day. Finally, early this year, after a Gallup Poll undertaken at the request of the Association had shown the public still widely believed that most of their weekly contributions were going to the Health Service, the Public Relations Department again embarked on a widespread poster and leaflet campaign.

Would it have been impossible for the Ministry of Health and the Ministry of National Insurance to have done all this themselves and made the Association's publicity efforts unnecessary? The Ministry of Health has its own publicity machinery, and if that is not sufficient it has access to the services of the Central Office of Information with all its grandiose apparatus of mass publicity through Press advertising, exhibitions, films, posters, and so on. One can think of many campaigns indulged in by the Central Office of Information which might seem to an outsider to have had less public justification than the work of public enlightenment about the Health Service which the B.M.A. has carried through at its own cost. One recalls the 32-page booklet which the Ministry of National Insurance—before its part in the scheme began—pushed through the letter boxes of every household in the country, making use of his Majesty's mails and postmen to do so. So far as mechanics go, the Government would have had no difficulty in getting across to the public a year ago the appeals for restraint and avoidance of "misunderstanding" which the Minister made last week.

Why was this not done? Was it that the Government was afraid, as many Governments may be afraid, to put the emphasis on duties as well as on rights? Or was it that the Government knew that the increased rate of weekly contributions was bound to be unpopular and was at least not averse from allowing the public to believe that the increase was due to what the Health Service generally and "the doctors" in particular were costing?

Changes in the Use of Hospitals

It does not always happen that one is able to commend important passages in a Ministry circular. But there has just been issued to regional hospital boards a circular (see p. 168) which is obviously on the right lines—though it may be justly said that it does not travel far enough along them. In discussing changes from general practitioner (cottage) hospitals to specialist hospitals, the circular states: "The Minister . . . would ask regional hospital boards to make sure that in carrying out their plans they are not depriving local patients of a valuable feature of the general practitioner (cottage) hospital. . . . It is, in the Minister's view, very valuable for the general practitioner service of the district when the family doctor has access to beds where patients of this type can be in his charge and he knows he can readily call upon the services of a consultant for a second opinion, and it is essential if the level of general practitioner medicine is to be maintained that the interchange of ideas between general practitioners and specialists should be facilitated by such consultation and by informal contacts on the occasion of regular visits from consultants to general practitioner hospitals. If such arrangements can be supplemented by the offer of a number of 'clinical assistantships' to general practitioners as part of a team in the district general hospital so much the better, but in the Minister's view the latter is not a substitute for the former, and if the result of reorganization is to deprive general practitioners of charge of hospital beds something valuable has been lost."

On the question of general practitioner maternity hospitals the following advice is given: "It has been the general practice to have obstetricians in charge of maternity departments and maternity hospitals. While recognizing the merits of this policy in the large unit where teaching and training is undertaken, the Minister feels that he should remind boards that, in the smaller types of maternity unit booking normal cases, staffing must necessarily vary. Where, in the larger of these, selected general-practitioner obstetricians have been in charge in the past, boards should carefully consider the position before altering the nature of the services provided and should be cautious about depriving general-practitioner obstetricians of the charge of maternity beds."

THE FIRST YEAR

MR. ANEURIN BEVAN'S REVIEW

The Minister of Health presented to a Press Conference on October 6 a review of the first year of the National Health Service. Great interest was taken in the occasion, and the pressure on Whitehall accommodation was such that some foreign and colonial correspondents had to be excluded.

Mr. Bevan began by saying that the launching of the Service had been accompanied by so much controversy, by emotions ranging from outright enthusiasm to destructive criticism, that it was thought well in the interests of the country to review the experience up to now, and to try to present a complete picture of what was going on. There was always the danger that such a picture might be obscured by sectional interests. One year was a short time in which to judge so great an experiment, but certain provisional judgments could be made. Pessimists had said that the Service would give rise to abuses, but after all it was a prerequisite of behaviour that people should be allowed to behave—should be given the opportunity of behaving—and from a study of such behaviour any necessary redirections might be made. It was true that there had been certain abuses, but on the whole the transition from the old system to the new had been accomplished with great smoothness, and he desired to pay his tribute to all concerned in such transition.

A Transferred Expenditure

The cost of the N.H.S., Mr. Bevan continued, must be regarded as a gigantic change-over from the private pocket to the public purse. In other words, the expenditure was not an addition to the total expenditure on health, but a transferred expenditure from the individual citizen to the nation. It was not the case, as was assumed by many people, that the cost was an additional burden. The people had been relieved of the necessity of making payments when in need of medical or other care, and the cost of payment for the whole "apparatus"—doctors, dentists, chemists, nursing, maternity—was laid upon the community as a whole. It was largely a redistribution. Various guesses had been made about what was spent on various health services by citizens on their own account before the Service started; it was probably more than £250 million.

Here he drew attention to an unfortunate confusion of language. There were the National Insurance Act, the National Health Service Act, and the former National Health Insurance scheme, and people seemed to assume that the N.H.S. was financed by the weekly contributions to national insurance. All that had happened was that the N.H.S. inherited that part of the old National Health Insurance contribution which was set aside for medical benefit, and which amounted to about £40 million a year; the remainder of N.H.S. expenditure fell upon national and local taxation.

No Army of Bureaucrats

Most of the administration was voluntary, and of this service there was no lack; the difficulty had been one of selection. To the members of governing boards of teaching hospitals, regional hospital boards, hospital management committees, local executive councils, and other bodies the administration had been entrusted. It was not run by an army of bureaucrats: It was this which accounted for the low administration costs—between 2½ and 3% of the total expenditure. This was made possible by the devoted service of 12,000 men and women drawn from all sections of the community. There was a central organization, but the bulk of the administration was pushed out to the periphery. The Central Health Services Council, whose function was to advise the Government on the various aspects of the Service, was very largely technical in character. Conditions of service and salaries were entrusted to Whitley Councils.

"It is obvious that a service of this sort, which provides free medical attention and drugs, is open to abuse both by those giving the service and those receiving it. But no abuse can arise unless it is connived at by two people—a member of the profession on one side and the patient on the other. When charges of abuse are made it must be recognized that they are made, not against the administration, but against some professional person who may have succumbed to the importunities of patients. There is evidence that abuse has taken place, but one does not read about the thousands of devoted professional men and women who go about their work in a proper fashion or the millions of people who receive proper attention."

One reason why abuses took place was because many thought they were paying a weekly contribution for the Service and were determined to get their money's worth. It should be widely known that expenditure increased just to the extent to which the Service was abused. It would be an advantage to have from every newspaper an appeal for the prudent and intelligent use of the Service, and such an appeal might well be made not only to the public but to the professions operating the Service.

Disciplinary machinery existed to deal with abuses, and had been operated. The chief sinners had been dentists and general practitioners. But he did not want to be misunderstood: the cases were few and far between, and when the vast volume of work done was considered it was extraordinary how few were the irregularities. The central tribunal to which the aggrieved person had a right of appeal had considered five cases—three dentists, one doctor, one optician. Two dentists had been removed from the Service, one for charging fees and one for failing to carry out treatment. Six other cases were awaiting hearing.

The Hospital Service

In the hospital service the shortage of nurses remained the prime difficulty. About 10% of available beds were denied to the Service for lack of nurses, but during the last year 8,000 full-time and 5,000 part-time nurses had been recruited, with the result that 7,000 additional beds had come into use. There had also been a complete change in the "climate" of the nursing profession; conditions of service and salaries had been improved, and nursing was now a real career. Between 40,000 and 50,000 more nurses were wanted.

All the hospital specialist services were contractual, either whole-time or sessional, and this should help to reduce the out-patient waiting-lists, especially as the appointments system was being rapidly extended. The new domiciliary specialist service was in operation, and during the first year 91,000 patients had been visited in their homes by specialists and 2,761 operations performed.

During the year 8,359 artificial limbs had been provided, 21,345 surgical boots, and 7,226 artificial eyes. He invited anyone who had sufficient curiosity to come and see what a great advantage had been conferred upon these recipients. As to the 5,071 wigs, he wished to remove the impression that wigs were dispensed on a beauty-parlour basis. They were provided on the prescription of a specialist, and two conditions were necessary: (1) that the baldness was due to accident, disease, or congenital causes, and (2) that the specialist declared the wig to be necessary. He deprecated the derision cast upon this part of the Service. To persons who had undergone a head operation leaving a serious scar, or who suffered from a scalp disease, a wig was as much a part of treatment as an artificial limb to others. It was a cardinal principle of the Health Service that medical care, attention, and appliances were provided where they were considered by the doctor to be needed.

"If he is not free to prescribe what is necessary, his liberty of action must be limited, in which case it would have to be said that he was free to prescribe so much, but not free to prescribe so much else. This would be almost impossible to administer. We must rest upon the principle that the doctor is free to prescribe what he considers to be necessary for the care and welfare of his patient."

The General Practitioner Service

The number of general practitioners in the Service was between 18,000 and 19,000. A great deal was heard in the early days about "direction" of doctors. Such direction had not taken place, nor was it ever intended. There was much discussion also about basic salary in "the early polemics of

the scheme." About 2,000 general practitioners were helped by fixed basic payments of £300. There were 57 doctors receiving special inducement payments (unpopular areas, etc.), and other claims were under review. The (mileage) payment for general practitioners in rural areas had been found to be too low, and £700,000 had been added to the fund to make up the deficiency. The doctors who had been approved for grants for training assistants numbered 374, and 250 doctors were utilizing post-graduate courses under grant.

"One of the worries of the scheme is over-prescribing. Over-prescribing occurs, not in the field of expensive drugs, but in ordinary things like aspirin and cotton-wool. The doctor may be protecting himself against a second visit by prescribing a little more in the first instance. He over-prescribes the prosaic medicaments. That is worrying us, and I make a serious appeal to general practitioners to be careful about this part of their work, and to patients not to be importunate. Most households are furnished with a small number of medicaments which every intelligent person knows how to use, and it should not be necessary to rush to the doctor every time something of that sort is needed."

Concerning health centres, the Ministry proposed to proceed steadily but cautiously. Some new buildings were being constructed, some old buildings adapted, and a few had been taken over which were there before. But it was desired to find out how people used health centres before embarking upon their widespread provision. The Ministry wanted to know how practical they were, what kind of health centres were most useful, and in what situations they would be most popular.

Mr. Bevan went on to speak of the dental, optical, and pharmaceutical services. About 8.5 million people had gone to the dentists for treatment, and the demand was rising again after a summer slackening. The normal demand might be assessed in about six months' time. There was a considerable "back log" to make up. The scale of payment was found to be too high and was cut by 20%. Some dentists resisted, but their resistance had not continued. It was here that most of the discipline had had to be exercised. As time went on he believed the position would improve. There had been an unanticipated rush for spectacles, and two pairs—sometimes three—had been prescribed rather too frequently. He had appealed to opticians on the matter and was satisfied that they had heeded. The production of lenses had been speeded up by about 50%, and three million lenses had been imported from "soft currency" areas. By the end of the year the production should be equal to the demand. As for the pharmaceutical services, the 14,000 chemists in the scheme had dispensed in the first year 187 million prescriptions.

The aural aids were now being produced at the rate of 2,000 a week, and about 29,000 had been issued. It was not only a question of producing the aid, but of teaching the recipients to use it properly, otherwise they gave up in despair. He hoped by the end of next year to have provided 150,000 aids.

The Overseas Visitor

Much had been made of the fact that people could come from abroad and make use of a service provided and paid for by the British people. There were two answers to that. In the first place people could not come from abroad merely in order to make use of the British Health Service: the immigration officers had been instructed to that effect. Secondly, any attempt to differentiate between an alien, a British citizen, and a person entitled by six months' residence to have recourse to the Service would be administratively expensive. He believed also that reciprocal arrangements would be made between Great Britain and other countries, and as reciprocity developed any sense of injustice would diminish.

Mr. Bevan was questioned on this point. He stated that American and Canadian visitors formed the highest proportion of those signing for temporary medical attention at one port where an analysis was made. Asked about reciprocal arrangements, he said that countries participating in the Brussels Pact were being approached. He thought that medical care should be part of the normal hospitality of any host country. If a visitor to this country had an accident he would, of course, be given medical attention, even if it involved prolonged treatment.

Mr. Bevan concluded his address by saying that the National Health Service began, as was inevitable, in an atmosphere of friction, controversy, doubt, and great hope. The first year had shown that a vast amount of good work was silently done, much relief afforded, but there was still friction at some points, and at some points shortages.

"It is obvious that in some parts of the country the general practitioners are overworked. It will take some years for the scheme to 'bed itself in.' More facilities will be needed before criticism dies down. One of the chief sources of our troubles here in Britain, as in many other parts of the world, is the increasing demand made upon hospital facilities by the aged sick. That is one of the great problems of modern civilization.

"I would have you realize that most of the shortcomings which have been revealed by the Service are not the result of the intrinsic difficulties of the Service, but of the overwhelming volume of need that the Service has disclosed. This will happen in other nations when they start the same kind of service. There has been in the past a vast amount of silent suffering, of preventable pain. What the National Health Service has done has been to make it articulate, and thus to make it readier of redress. In that respect, I believe, we have made a great start."

Mr. Bevan Questioned

A question asked of Mr. Bevan was, "Do you think the pay of general practitioners is disproportionately low when compared with the pay of dentists and opticians?" He replied that he could not accept that. When thinking of the payment to dentists it must be remembered that 52% of the gross earnings were regarded as expenses. The dentist had to employ his mechanics and provide his apparatus. It was not easy to fix the scales for dentists' remuneration, and for a while there had to be a period of experiment. The endeavour was to make it profitable for dentists to save teeth rather than extract them.

In reply to a further question about remuneration, he said that the Spens recommendations for the remuneration of general practitioners had been carried out. Discussions were proceeding with the British Medical Association, and before he made a statement about general practitioner remuneration he would like to have the main facts agreed with the members of the profession. "So far there is conclusive evidence that we have more than honoured the Spens recommendations."

Asked about a health tax, he said that he thought the Chancellor might try to find some additional revenue in view of the cost of the Service. If by "tax" was meant payment by the patient at the moment when the patient needs treatment the Ministry had set its face against it.

Questioner: That means a possibility of increasing the health contribution part of national insurance?

Mr. Bevan: The possibilities of taxation are infinite

The Minister added that the original estimate of the cost of the Service was based upon scales of remuneration far lower than those which had in fact been paid. In the hospital service alone 60% of the expenditure was on wages and salaries. The pay of medical officers, nurses, midwives, and domestic staffs had been increased.

In another reply he said that Sir Henry Cohen had been asked to preside over a committee to draw up a list of drugs which the general practitioner could prescribe and outside which he need not go except in special cases

Asked how far the Service had furthered the progress of medical science, he said that much valuable case history, not previously available, was being collected. A committee would be appointed to get agreement about the names of diseases. He was also asked whether any analysis had been made of the time a general practitioner spent in filling up forms. He replied tartly that he had no such analysis, nor had he any analysis of the time it took a general practitioner, before the Service came in, to make out his bills.

He was also asked about his attitude to the Trade Union Congress resolution calling for the immediate establishment of a hundred health centres. He replied that it would take its place in the queue along with other such resolutions. Health centres must not be regarded as being at the head of the queue.

Other Statistics of the Service

Figures in addition to those mentioned by Mr. Bevan were contained in a sheet handed to each person attending the conference. All the figures relate only to England and Wales:

Prescriptions

Estimated proportion of articles prescribed and supplied:	
Mixtures	40%
Tablets, pills, etc.	20%
Ointments	5%
Proprietary preparations	12%
Appliances (bandages, dressings)	7%
Miscellaneous (lotions, gargles)	16%

Hospitals and Specialist Services

Hospitals taken over	2,688
from local authorities	1,545
voluntary	996
teaching hospitals	147
Beds	501,738
teaching hospitals	26,552
others	475,186
Hospital clinics taken over	591
from local authorities	481
voluntary	108
teaching	2
Nursing and midwifery staff engaged in hospital service	149,783
whole-time	126,955
part-time	22,828

Disciplinary Service Committees

			Withdrawals of removals from list
Medical (18,585)	Proposals for removal from list	15	1
	Fines, etc.	15	
	Warning letters	28	
	No action	72	
Dental (9,401)	Proposals for removal from list	6	2
	Fines, etc.	85	
	Warning letters	27	
	No action	106	

N.H.S. IN SCOTLAND

The following approximate figures issued by the Department of Health for Scotland complement those given for England and Wales by Mr. Bevan.

Number of people on doctors' lists (96.6% of population)	4,954,897
General practitioners within the Service (plus 27 assistants on lists)	2,394
Chemists within the Service	1,749
Prescriptions dispensed in first year (estimate)	14,950,000
Doctors receiving basic payments of £300	145
Doctors receiving special inducement payments	30

Optical Services

Ophthalmic medical practitioners in the Service	77
Ophthalmic opticians (all)	848
Dispensing only (all)	23
Spectacles supplied and paid for	680,891
Estimated number of people receiving two pairs of spectacles (30%) (680,891 pairs for 530,880 persons).	

Dental Services

Cases received by Dental Estimates Board for approval or payment	1,380,527
Dentists in Service (practically all)	1,170

Hospital and Specialist Services

Appliances through hospitals. Total of all main types issued including artificial limbs (very roughly)	25,000

CHANGES IN THE USE OF HOSPITALS

GENERAL PRACTITIONER HOSPITALS

The Ministry of Health has issued the following circular (R.H.B. (49) 132):

Under the National Health Service (Functions of Regional Hospital Boards, etc.) Regulations (S.I. 1948, No. 60) the Minister's powers for planning and developing the hospital and specialist services were, subject to direction, delegated to regional hospital boards and boards of governors. It is therefore competent to the board, subject to direction, to make changes in the use of hospitals without prior reference to the Minister. The Minister is aware that boards have been considering changes of user in the hospitals under their administration, and it is right and proper that they should do so.

The Minister is anxious to avoid intervening where boards have arrived at a decision after full consideration, but the delegation of powers is subject to direction on his part, and under Section 6 (4) of the Act he is bound in using hospitals transferred to him by the Act "so far as practicable" to "secure that the objects for which [they were] used immediately before the appointed day are not prejudiced by the provisions of this Section" (i.e., transfer to the Minister).

He cannot, therefore, ignore representations made to him by members of the public and the profession, and may feel bound at any time to call upon a board to report to him their reasons for adopting their new policy. It is undesirable for this to happen after the actual process of change has been begun, and he thinks boards will find it useful, where a proposal is likely to give rise to substantial local or professional opposition, to keep the Department informed of their plans at all stages.

Boards may find useful the following indication of the Minister's views on a number of matters that arise in connexion with changes of use of hospitals. The principal factors are, of course, (1) the possible loss of service to patients, (2) the disturbance of medical staff.

Change from One Specialty to Another or from a General to a Special Hospital

In the case of infectious-disease and smallpox hospitals, which tend to be redundant owing to centralization, little difficulty is expected provided that regional boards have assured themselves that the new centralized facilities meet anticipated needs and have done their best to secure that the staffs of the redundant hospitals are not prejudiced by the change.

In the case of other changes of this nature—i.e., from one special use to another or from general to special hospital—the difficulties encountered may be more serious. In particular, where a hospital of long-standing repute is concerned, the board should see that the medical staff of the hospital has free opportunity of having its views considered by the board or their planning committee, orally if possible. An open meeting at which the proposal can be explained and members of the public can express their views may sometimes be desirable, particularly where it is proposed to use a small local general hospital for other purposes, since the local loyalty that such hospitals command must not be ignored even where reorganization is expected to produce greater medical efficiency.

Change from General Practitioner (Cottage) Hospital to Specialist Hospital

Local loyalty is again a factor of great importance. In the past general practitioner hospitals have, owing to the uneven distribution of consultants, been compelled at times to undertake work for which they were not properly equipped, and they have often been criticized for trying to do too much. The introduction of the National Health Service, and in particular the present review of establishments, has given an opportunity for improving this state of affairs and for developing hospitals staffed by consultants even in smaller centres.

The Minister is whole-heartedly in favour of development in this direction but would ask regional hospital boards to make sure that in carrying out their plans they are not depriving local patients of a valuable feature of the general practitioner (cottage) hospital—i.e., its use as a local hospital to which the general practitioners of the neighbourhood can admit patients.

who require treatment within the scope of a general practitioner but who, for various good reasons, cannot be treated at home. It is, in the Minister's view, very valuable for the general practitioner service of the district when the family doctor has access to beds where patients of this type can be in his charge and he knows he can readily call upon the services of a consultant for a second opinion, and it is essential if the level of general practitioner medicine is to be maintained that the interchange of ideas between general practitioners and specialists should be facilitated by such consultation and by informal contacts on the occasion of regular visits from consultants to general practitioner hospitals.

If such arrangements can be supplemented by the offer of a number of "clinical assistantships" to general practitioners as part of a team in the district general hospital so much the better, but in the Minister's view the latter is not a substitute for the former, and if the result of reorganization is to deprive general practitioners of charge of hospital beds something valuable has been lost.

In particular the Minister wishes regional boards to guard against the feeling that local cottage hospitals are merely buildings to be used as additional accommodation for relieving pressure on beds at the district general hospital of the group. There may be cases where it will improve the efficiency of the group organization for a general practitioner hospital within that group to be used as a specialist department—e.g., as a maternity unit or as a recovery hospital or a geriatric unit. But if the loss to the district of the "general practitioner beds" is to be avoided the board should make arrangements for the general practitioners of the district to have charge of a number of beds in the district hospital or elsewhere, which can then serve, in the way described above, as a "general practitioner wing."

General Practitioner Maternity Hospitals

It has been the general practice to have obstetricians in charge of maternity departments and maternity hospitals. While recognizing the merits of this policy in the large unit where teaching and training is undertaken, the Minister feels that he should remind boards that, in the smaller types of maternity unit booking normal cases, staffing must necessarily vary. Where, in the larger of these, selected general-practitioner obstetricians have been in charge in the past, boards should carefully consider the position before altering the nature of the services provided and should be cautious about depriving general-practitioner obstetricians of the charge of maternity beds.

In the smaller cottage hospital type of provision where general practitioners attend their own patients a selected general-practitioner obstetrician should have the general oversight of the unit.

Boards should endeavour to link the smaller units with the nearest maternity department and make readily available to the general-practitioner obstetricians concerned the consultant obstetric services of the larger hospital.

SPECIMENS IN THE POST

The Post Office has complained recently that packages containing specimens sent through the post for medical examination or analysis have in some cases been insecurely packed and fastened. In the interests of public health and the prevention of risk to Post Office staff great care should be taken to see that specimens sent through the post are securely packed, and that the containers are not likely to be broken or their contents spilt owing to corks and stoppers coming out. A new type of container is to be used, but even so it would not be safe unless securely fastened and well packed. The Post Office regulations are as follows:

Articles Sent for Medical Examination or Analysis

Deleterious liquids or substances, though otherwise prohibited from transmission by post, may be sent for medical examination or analysis to a recognized medical laboratory or institute, whether or not belonging to a public health authority, or to a qualified medical practitioner or veterinary surgeon by letter post, but on no account by parcel post, under the following conditions:

(1) Any such liquid or substance must be enclosed in a receptacle, hermetically sealed or otherwise securely closed, and this receptacle must itself be placed in a strong wooden, leather, or metal case in such a way that it cannot shift about, and with a sufficient quantity of some absorbent material (such as sawdust or cotton-wool) so packed about the receptacle as absolutely to prevent any possible leakage from the package in the event of damage to the receptacle. The packet so made up must be conspicuously marked FRAGILE WITH CARE and bear the words PATHOLOGICAL SPECIMEN.

(2) Any packet of the kind found in the parcel post, or found in the letter post not packed and marked as directed, will be at once stopped and destroyed with all its wrappings and enclosures. Further, any person who sends by post a deleterious liquid or substance for medical examination or analysis otherwise than as provided by these regulations is liable to prosecution.

(3) If receptacles are supplied by a laboratory or institute, they should be submitted to the Postal Services Department, General Post Office, London, E.C.1, in order to ascertain whether they are regarded as complying with the regulations.

VARIATION IN CAPITATION FEES

The capitation fees paid to general practitioners vary from one executive council area to another according to the prior payments made in the different areas, such as for basic salary. The following table from a report of the Management Committee of the Executive Councils Association (England) summarizes the distribution of the capitation fees paid by 122 executive councils in England:

Amount per Person	No of Councils
s. d.	
14 9	1
15 6 to 16 0	5
16 0 to 16 6	13
16 6 to 17 0	84
17 0 to 17 6	18
17 10	1
Total	122

ENTRY INTO PRACTICE

Noting that there is "widespread dissatisfaction throughout the profession" on the existing methods of entering general and consultant practice, the Medical Practitioners' Union has prepared a report entitled "Entry Into General Practice," which has been circulated to members of the medical profession.

The report considers that the medical student will tend to favour specialization, for the discrepancy between the earnings of the specialist and those of the general practitioner is "quite out of proportion to the relative value of each to the community." Nevertheless, the comparatively few specialist posts available will force the average medical student into general practice.

General Practice

The difficulties of the assistant are discussed, and the report says that the principal has every reason to postpone taking his assistant into partnership. To remedy this the M.P.U. proposes that the period during which a principal could have the benefit of an assistant should normally be limited to two years; he should then take a partner or be required to reduce his list. Moreover, the remuneration and conditions of work for assistants should be established.

Discussing the "relatively poor prospects" of the doctor who enters general practice by putting up his plate, the report recommends that the Medical Practices Committee should become a central employment agency, and should find suitable openings for anyone wishing to start general practice. In the under-doctored areas new entrants should be helped financially in three ways:

"(a) The local executive councils should be empowered to advance money to newcomers for their living expenses and for the purchase of cars, equipment, and surgery premises. The sums advanced would be gradually repaid over a long period by suitable deductions from the

quarterly cheques. (*b*) The allocation committees of the local executive councils should make full use of their powers to assist a newcomer in the acquisition of patients. (*c*) As a corollary the need for the fixed annual payment would be reduced and ultimately disappear."

When a doctor dies or retires the allocation committee should transfer his patients to existing practitioners or newcomers according to the needs of the doctors and the proximity of the patients to their surgeries, though the patient could still change to another doctor if he wished.

The M.P.U. advocates an expense allowance on a sliding scale and a graduated capitation fee. The payments for expenses would be a first charge on the Central Fund, and the capitation rate would therefore be reduced. The capitation fee should be 30s. a patient for the first 2,000 and 20s. for the rest.

Specialist Practice

The grade of senior hospital medical officer should be abolished by the Minister except in special circumstances. Regional hospital boards should create a medical "establishment" for each hospital, and the posts should be filled only by those of the proper grade. They should offer whole-time posts to specialists where possible.

A central board to hear grading appeals should be set up.

DOMICILIARY CONSULTATION

The Ministry has informed the Joint Committee representing consultants and specialists that the present arrangements for domiciliary consultations are not entirely satisfactory, and that direct contact between general practitioners and consultants is more workable.

The Central Consultants and Specialists Committee is therefore seeking the views of its constituents, so that it may report to the Joint Committee on whether they would prefer direct contact between general practitioners and consultants or domiciliary consultations to be arranged as at present through the hospital bureau.

HEARD AT HEADQUARTERS

The Minister Expounds

Mr. Bevan's first press conference on the Health Service was quite a personal success. There was no vituperation and little rhetoric. His account was predominantly factual, his delivery often deferential, and his approach almost solicitous to the representatives of "the most prostituted press in the world." As is customary on these occasions, he glossed over the defects of the scheme and painted a tranquil Impressionist picture of one corner of the English scene to-day. Though evasive at times, he was never abusive, and gave the journalists plenty of opportunity to fire questions at him. His grasp of detail in his replies was impressive; the Ministry officials at his side rarely whispered any information to him, and he had usually started on his reply before they had. It was a performance skilfully adapted to the audience—quite different from those Parliamentary "triumphs" that bring a glow to the cheeks of Labour back-benchers. We came away with heavenly choirs singing in our ears.

Hazards of General Practice

A correspondent asks, as have many others, whether there should not be a code of behaviour for patients, and he gives several instances of patients' conduct that the code would no doubt exclude. A young man recently looked in when passing at 1 a.m. on his way home from a dance—to consult the doctor about insomnia. Another man arrived at 8.30 p.m. in his own car asking the doctor to visit his wife, saying that she had a spot on her leg. When the doctor asked why she hadn't come in the car with her husband, he replied that her hair was in curlers. A more pathetic story was that of a lady who demanded an immediate visit six miles away because her father's will was disappointing.

Questions Answered

Superannuation and Repayment for Drugs

Q.—*When I am reimbursed for drugs and appliances on the special list supplied by me to my dispensing patients I suffer superannuation deduction on the amount received. Why is this? The money I receive is a repayment and not remuneration.*

A.—During the early discussions with the Ministry it was claimed that only so much of the remuneration as related to dispensing should count for superannuation and that the actual cost of the drugs should be ignored. This logical solution would have involved practitioners and executive councils in a great deal of work; moreover, to segregate the cost of drugs where the capitation method is accepted would be difficult, and to do so only for those practitioners who are paid by the other method would lead to undesirable discrimination. In addition, 8% of Government money is attracted to the whole amount. For these reasons it was decided not to oppose the present arrangements whereby superannuation contributions are paid on the actual amounts received.

AUSTRALIAN HEALTH SERVICE

PRESCRIBING ACT INVALID

The Australian High Court declared on October 7 by a majority of four to two that Section 7a of the Pharmaceutical Benefits Act is invalid (*The Times*, October 8). This section requires doctors to use a Government prescription form when prescribing free medicine.

The action had been taken by the Federal Council of the B.M.A. in Australia, which filed a writ on July 25 in the High Court challenging the constitutional validity of the Government's free medicine scheme.

The court found that the clause compelling doctors to operate the service amounted to a form of civil conscription, which is forbidden by an amendment to the constitution approved in 1946 empowering the Commonwealth Government to provide social services, including medical benefits. The Chief Justice held that if the clause were deleted the rest of the Act was valid and could be operated as a voluntary scheme.

ANNUAL CONFERENCE OF REPRESENTATIVES OF LOCAL MEDICAL COMMITTEES

MOTIONS AND AMENDMENTS FROM LOCAL MEDICAL COMMITTEES

Standing Orders of Conference

MOTION by Worcester: That the second sentence of Standing Order (1) be amended to read as follows:

"That this Conference shall ordinarily be held in the month of October."

Remuneration

MOTION by Southport: That this Conference views with grave concern the delay which is incurred in the satisfactory settlement of remuneration of general practitioners, and demands that any increase be retrospective to July 5, 1948.

MOTION by Glasgow: That this Conference deplores the delay of the Ministry of Health in the negotiation of the terms of remuneration, and affirms that further delay may precipitate a complete breakdown of the National Health Service.

MOTION by Middlesex: That this Conference is strongly of opinion that full recognition of the claim of general practitioners in the National Health Service for increased remuneration on the basis of present-day values be established forthwith with the Ministry of Health.

Temporary Residents

AMENDMENT by Lothians and Peebles: That paragraph 44 of the Report of the G.M.S.C. be amended so that the words "advice and/or" be inserted between the words "medical" and "treatment."

MOTION by Isle of Wight: That this Conference is of the opinion that the submission of Forms E.C.7 and 8 to a patient's own doctor serves no useful purpose, whereas a detachable slip on Form E.C.19, bearing a diagnosis, which the patient could hand to his doctor, would be of clinical value.

Basic Salary

MOTION by Lancashire: That this Conference instructs the General Medical Services Committee to consider the question of basic salaries in all its aspects with a view to reopening discussion of the subject with the Minister of Health at the earliest opportunity.

Filling of Vacancies Caused by Death or Retirement

MOTION by Isle of Wight: That this Conference is of the opinion that it would appear desirable that there should be closer contact between the Medical Practices Committee and the Local Executive Councils, together with their Local Medical Committees, prior to the filling of vacancies.

MOTION by Lancashire: That the appointment of a successor to a practice declared vacant should be made by the Local Executive Council in consultation with the Local Medical Committee without submission to the Medical Practices Committee.

MOTION by Lancashire: That the machinery for hearing appeals by unsuccessful applicants should be investigated forthwith, as the delay which generally occurs under present procedure endangers the succession to the practice and the continuity of the medical services.

MOTION by Devon and Exeter: That all applications for entering practice be considered by the Medical Practices Committee in relation to any restrictive bond

Vaccination and Immunization

MOTION by Devon and Exeter: That this Conference protests most strongly against the long delay in payments of fees for vaccination and inoculation.

MOTION by Gateshead: That this meeting fully endorses the action of the G.M.S. Committee in informing the Ministry of Health that it will take no steps to discourage the refusal of the return of reports of vaccination and immunization pending the satisfactory conclusion of negotiations on this point.

Medicines and Appliances for Doctors' Surgeries

MOTION by Buckinghamshire: That the proposal that doctors should be allowed to order on official prescription forms stocks of medicines and dressings for emergency use in surgeries be strongly and urgently pressed for; and that, in addition, permission be sought for the extension of this system to all drugs and appliances which are to be administered or applied by the practitioner in person.

Specially Expensive Drugs and Appliances

MOTION by Buckinghamshire: That the present inordinate delay in the return of scrips from dispensing doctors by the Central Pricing Committee which require the sanction of the Minister before payment is wholly unjustifiable; and that in future their return should take place within two months.

Prescription Books

MOTION by Worcester: That the reconstructed Prescription Book be provided with carbon paper.

Mileage in Maternity Cases

MOTION by Isle of Wight: That in the opinion of this Conference the proposed mileage payment in respect of maternity services is inadequate and should be increased, and that the payment should come from the same source as the payments for maternity services.

MOTION by Buckinghamshire: That maternity mileage should be paid from the same source as other payments for maternity work.

MOTION by Buckinghamshire: That this Conference disagrees with a single payment of three shillings per mile for each maternity case booked, and asks for a reinvestigation of the matter with a view to payments for journeys actually carried out, on the lines ruling before July 5, 1948.

Medical Services Committee Procedure

MOTION by Norfolk: That this meeting considers that an independent chairman with legal qualifications should be appointed to preside at Medical Services Committee meetings.

MOTION by Isle of Wight: That this Conference is of the opinion that, as the regulations governing the consideration of complaints against the medical practitioner do not provide, as did the old National Health Insurance Benefit Regulations, for similar action against the patient, the Minister of Health should be pressed to provide for it under the new Service.

Specialization in General Practice

MOTION by Eastbourne: That this Conference is of opinion that doctors should be paid an adequate fee for performing circumcision within two weeks of birth (not less than £1 1s.).

General Practitioners and Hospital Work

MOTION by Cambridgeshire and by Sunderland: That this Conference protests against the present policy of exclusion of general practitioners from the clinical assistant type of post in teaching and other hospitals. It urges that every effort should be made to get the number of these posts greatly increased.

MOTION by Hastings: That this Conference strongly disapproves of the present regulations whereby a practitioner not in contract with a Regional Hospital Board is not allowed to attend his private patients in the private wards of a hospital.

MOTION by Kent and Canterbury: That this Conference, having given attention to the circular letter R H B (49) 132 (*Supplement* October 15, p. 168), considers that the advice given therein by the Minister of Health to regional hospital boards with regard to proposals for the change of function of cottage hospitals, the continued provision of beds which shall be in the charge of general practitioners (including maternity beds in the charge of general-practitioner obstetricians), and the suggested establishment in district general hospitals of posts as clinical assistant available to general practitioners is sound and acceptable. The Conference suggests to local medical committees that they shall take every opportunity to press in their areas for action to be taken by regional hospital boards and hospital management committees in accordance with the advice given in this circular letter.

General Practitioners and Special Departments of Hospitals

MOTION by Dewsbury: That this Conference feels that it is contrary to the interests of the patient that general practitioners should be excluded from certain departments of hospitals and that they should have direct access to such departments e.g. the *X*-ray Department, the Physiotherapy Department and the Pathological Laboratory.

General-practitioner Specialists

MOTION by Isle of Wight: That this Conference strongly deprecates the exclusion of large numbers of general-practitioner specialists from their hospital work, and is of the opinion that their status should be recognized and that they should be allowed to continue their work, as was promised by the Minister of Health

Remuneration of General Practitioners on Staffs of Cottage Hospitals

MOTION by Isle of Wight: That this Conference is of the opinion that £25 per occupied bed is totally inadequate, unless such items as anaesthetics and assistance at operations carry additional payment.

Superannuation

MOTION by Leicestershire and Rutland: That, as early as practicable after April 5 of each year, a single statement should be available to each general practitioner in the Service showing the total amount deducted in respect of superannuation contributions from all sources.

Grants for Training Assistants

MOTION by Middlesex: That this Conference is of the opinion that it should be obligatory for a formal contract to be entered into between the trainee assistant and the doctor undertaking the training.

Emergency Treatment Following Dental Operations

MOTION by Gateshead: That the G.M.S. Committee be instructed to continue to press for a payment from the Dental Estimates Board to practitioners called upon to deal with dental haemorrhage.

Treatment of Members of H.M. Forces on Leave

MOTION by Isle of Wight: That this Conference is of the opinion that immediate steps should be taken to ensure that the names of Service patients are restored to the list of their previous doctor on demobilization, as was done prior to July 5, 1948.

Frivolous or Unjustified Emergency Calls

MOTION by Gateshead: That rules for the conduct of patients, with appropriate disciplinary machinery, should be introduced forthwith.

Medical Card

MOTION by Lothians and Peebles: That provision be made for patients to obtain a new Medical Card to replace a lost one, as was formerly possible under the N.H.I. Acts.

Maternity Medical Services

MOTION by Gateshead: That where maternity hospitals do not fully implement their responsibilities to their booked patients during pregnancy, the general medical practitioner who is called upon to undertake such responsibilities shall be entitled to some proportion of the maternity fee.

Economy in Prescribing

MOTION by Inverness: That a Commission should be set up to go into the nomenclature of drugs and the standardization of bulk in packages with a view to eliminating waste and extravagant prescribing.

Status of General Medical Services Committee

MOTION by Bristol: That this Conference, wishing to clarify the position of the General Medical Services Committee, and in view of the statement that it is a B.M.A. Committee, emphasizes that the G.M.S. Committee is responsible to this Conference only and is in no way responsible to the Representative Body.

General Practitioner Refresher Courses

MOTION by Isle of Wight: That in the opinion of this Conference practitioners should have free choice of venue for refresher courses.

Admission to Medical List of Doctors from Adjoining Areas

MOTION by Middlesex: That this Conference views with alarm the practice of admitting practitioners from an adjoining area to an Executive Council's list irrespective of the distance from the applicant's surgery to the area of practice, and instructs the General Medical Services Committee to discuss the matter with the Medical Practices Committee so that a reasonable limit of distance may be set.

Correspondence

Entry to General Practice

SIR,—The Medical Practices Committee's first report (*Supplement*, September 10, p. 128) states under "Admissions to Medical List" (p. 129): "*(a) Applications to Start Practice.* . . . The committee in carrying out its statutory duty has, however, *been compelled to admit applicants to the medical list against* the advice of some executive councils that they be refused . . . but it of course remains the function of the executive council concerned *after* [my italics] his admission to its list to satisfy itself that the practitioner's arrangements for attending the patients he accepts are adequate."

Recently the executive council of this area advised the refusal of an applicant who gave as his surgery location an address at least six miles distant from the nearest point in the area, with surgery hours which made attendance by patients with ordinary working hours impossible. Between the area in which the surgery lay and this area there intervened a three-mile-deep belt of another area, so that the applicant's practice could not be said to be in an adjoining area. The whole district is urban, and the distribution and number of doctors are well up to average.

The Medical Practices Committee, however, overruled the advice of the executive council, and admitted the applicant to the list. (Having got so far, the applicant then withdrew from the medical list, and solved the problem.)

Such a decision makes nonsense of the latter part of the paragraph quoted above. Imagine the reaction, particularly of the non-medical members of an executive council, if asked to put into motion the machinery for removing a name from the medical list under such conditions.

May I add that my personal interest is solely that of a member of the local executive council. I did not enter the N.H.S.—I am, etc.,

Rochdale. L. KILROE.

Freedom and Closure

SIR,—I feel we need some clarification on the issues involved in serving on bodies connected with the National Health Service. One in particular is the question of open or closed areas. Is it not true that the principle of negative direction instead of positive direction was wrung out of the Minister? Does this or does this not mean that instead of young doctors being posted to under-doctored areas they would be encouraged to go there because other areas would be considered adequately doctored and would be closed? Is it not therefore nonsense to talk about the closing of areas in this case being a loss of freedom? Surely we need some expression of our policy in this matter to clear the minds of some of our more emotional and muddle-headed colleagues.—I am, etc.,

London, W.C.1. J. L. MCCALLUM.

Payment for Dispensing

SIR,—In our practice, as no doubt in most rural practices where drugs are supplied, we felt that the capitation fee for this service—at present 6s. 6d.—was going to prove grossly inadequate. I wrote therefore to the Association officers, who replied that the fee had been agreed by the Rural Practitioners Subcommittee, but that I could, if I wished, use the method for payment that chemists used.

At the beginning of this year we began to do so. The first six months of the year showed how right we were in our fear that the capitation fee was too small. We are now, in fact, being paid almost exactly double what we would be paid by the capitation fee, but it involves a considerable amount of extra work in the matter of writing the prescriptions, collecting and posting them, and sometimes considerable correspondence between us and the wholesale chemists on those occasions when the committee feels unable to make a price.

For the second six months of the year, however, a new method has been imposed on us, and greatly increased time has to be spent in the sorting and pricing of the prescriptions themselves. The extra work that results from the monstrous inadequacy of the capitation fee now amounts to a considerable proportion of our time. No medical practitioner in his right mind can enjoy the extra clerical work involved in this absurd method of paying him an adequate amount for this work. It is high time that the capitation fee was reviewed. Be it noted that the amount spent on medicines per patient by practitioners in the city areas is so far very considerably in excess of the sum we are using.

If an adequate sum is offered to the doctor, it would be *thankfully accepted. It would relieve the doctors of all this* pointless and irritating extra work and would enable the pricing committees to rid themselves of a vast quantity of their work and presumably to reduce their staffs.—I am, etc.,

Settle, Yorks. W. A. HYSLOP.

Payment of Locums

SIR,—May I suggest that "An Occasional Locum" (*Supplement*, September 17, p. 140) has a chip on his shoulder? When I did locums in 1923 I was very glad to get 5 guineas per week. I must now pay nearly three times as much to a deputy, who is therefore at least as well off as I was, without allowing for the fact that the 1923 £ was of much less value than the 1914 £.

My gross income now is a little in excess of £2,000 per annum. What holiday does "An Occasional Locum" think that I would or could have were I obliged to pay a locumtenent at the rate of £1,050 net as well as continuing to maintain for his use an expensive, fully manned establishment? (I, too, am "on call for 24 hours," but for every day in the year apart from my well-earned and inevitably costly holiday.)

While I am on the subject of locums may I suggest that these relatively junior people would do more to earn their stipend if they would treat the equipment of their absent employer as carefully as they would if it were subject to its owner's daily inspection, and if they would realize that their contempt for the alphabet causes a great deal of subsequent trouble. Having recently returned from a holiday I am trying to cope with abnormally large surgeries made up in great part of patients who would not come while a stranger occupied my chair, and of others who have come to make quite sure that "the young doctor" knew what he was talking about in their own cases. These busy surgeries are made much more harassing by the necessity to hunt through my cabinets to find "F.M.R.s" which were not accurately replaced.—I am, etc.,

ONE WHO DISLIKES BEING CALLED AN EXPLOITER.

Correction.—In the last sentence of the letter headed "Doctors and Dentists" by Dr. W. Ferguson Mackenzie (*Supplement*, October 8, p. 163) the word "inequities" was printed in error as "iniquities."

THE MEDICAL ASSOCIATION OF EIRE

Notice is hereby given to the members of the Medical Association of Eire (I.M.A. and B.M.A.) of the following proposed changes in the by-laws of that body.

The words "Division," "Division and," and "Division or" shall be deleted wherever appearing in the by-laws.

By-law No. 5, subparagraph of By-law 13, By-law 14, By-law 17, By-law 24 (*b*) (v) shall be deleted.

By-law No. 9 shall be deleted and the following substituted therefor:

(*a*) On and after the 1st January, 1950, the annual subscription to the Association shall be four guineas, or such sum as may be decided on by the Central Council, provided that

(i) the annual subscription payable by a member admitted to membership before the expiration of two years from the date of his registration under the Medical Acts for the time being in force in Eire shall be two guineas, or such sum as may be decided on by the Central Council until the 31st December next occurring after the expiration of four years from the date of such registration.

(ii) Any member who has been for not less than forty years a member of either the Irish Medical Association or the British Medical Association and the Medical Association of Eire (I.M.A. and B.M.A.) shall pay an annual subscription of two guineas, or such sum as may be decided on by the Central Council.

(iii) Any member of not less than ten years' standing of either the Irish Medical Association or the British Medical Association and the Medical Association of Eire (I.M.A. and B.M.A.) who has definitely and permanently retired from the active practice of the medical profession, and has signed and transmitted to the Treasurer of the Association a declaration to that effect, shall pay an annual subscription of two guineas, or such sum as may be decided on by the Central Council.

(iv) Any member admitted on or after the 1st July in any year shall pay only half his current subscription for that year.

(v) Any member who holds an appointment as a Commissioned Officer in the Defence Force in Eire shall pay an annual subscription of three guineas, or such sum as may be decided on by the Central Council.

(vi) A husband and wife both being members shall pay a subscription of £5 12s. 6d., or such sum as may be decided on by the Central Council.

(*b*) For the purpose of this By-law a member shall be deemed to reside in that place in which his ordinary place of abode is situate at the time at which, according to the Articles, his subscription is considered due.

That By-law No. 18 (*a*) shall be deleted, and the following By-law be substituted therefor:

The following shall be the special Groups of the Association until the Central Council shall otherwise determine: (i) Dispensary Medical Officers' Group; (ii) Public Health Medical Officers' Group; (iii) Medical Officers of Mental Hospitals' Group; (iv) Medical Officers of Voluntary Hospitals' Group; (v) County Hospital Surgeons' Group; (vi) Whole-time Medical Officers in the service of the Government of Eire: (vii) Private Practitioners' Group: (viii) Radiologists' Group; (ix) Ophthalmic Surgeons' Group; (x) Medical Officers of Local Authorities' Hospitals, not provided for in any other Group; (xi) Pathologists' Group.

Members of the Association may register in any one of the foregoing special groups, if eligible, and shall remain a member of such special group until notification is received of his wish to transfer to another special group, or to resign from his or her original special group. No member may elect to be included in more than one of these groups.

That By-law No. 18 (c) be amended by adding the words: "(xi) Pathologists' Group: Any member of the Association who is a Pathologist."

That By-law No. 23 shall be deleted and the following By-law be substituted therefor:

The Central Council shall consist of:

(*a*) The President, the immediate Past-president, the Vice-president, the Chairman (if elected), the Honorary Treasurer, and the Honorary Secretary of the Association.

(*b*) Members of the Association elected by their respective Branches for one year in the following proportions: Branches consisting of not more than fifty members shall be entitled to elect one representative. Branches consisting of more than fifty members, and not more than one hundred members, shall be entitled to elect two representatives. Branches consisting of more than one hundred members shall be entitled to elect one additional representative for each additional one hundred members or proportion thereof, provided that such proportion exceeds seventy-five in number.

(*c*) Members of the Association representing Special Groups elected in manner hereinafter stated for one year and who shall be entitled to representation on the same numerical basis as the Branches, as more particularly set out in the preceding paragraph.

Notwithstanding anything hereinbefore contained the Council shall have power to increase or decrease the number of Special Groups.

(*d*) Seven members of the Association elected for one year by the Annual General Meeting.

(*e*) Such members of the Association, not exceeding six in number, as may be co-opted for the remainder of the year by the members of the Central Council specified in sub-clauses (*a*) to (*d*) inclusive as above at their first meeting.

That By-law No. 24 (*a*) (ii), (iii), and (iv) be deleted and that the following By-law be substituted:

Members of Branches shall each year during the month of March hold an Annual Meeting of the Members of each Branch at which representatives to the Central Council shall be elected as hereinbefore provided. The election of a Branch representative or Branch representatives at such meetings shall be by secret ballot in which only the members present shall be entitled to vote. A statement as to the result of the ballot signed by the Chairman of the Branch at which such election shall have been held, as hereinbefore provided, shall be conclusive evidence of the election of representative or representatives of the said Branch to the Central Council.

That By-law No. 27 be amended as follows:

After the words "By-law 25" insert:

If the Branch or Group do not appoint a successor, then in that event the Central Council shall be at liberty to fill the vacancy by appointing a representative of the Branch or Group.

That By-law No. 33 be deleted and the following be substituted therefor:

The Central Council shall meet not less than twice a year and shall be presided over by the President of the Association or in his absence by the Vice-president, unless a Chairman of the Central Council and of the Executive Committee shall be elected as hereinafter provided.

If the Central Council by a majority vote decide in any year to elect a Chairman, then, in that event, the Central Council shall be entitled to elect from amongst their members a Chairman of the Central Council who shall hold office for the same period as the Honorary Secretary and Honorary Treasurer of the Association. The Chairman of the Central Council when elected shall also be deemed to be Chairman of the Executive Committee and shall preside at all meetings of the Central Council and of the Executive Committee.

That By-law No. 35 be amended by deleting the figure "4" and substituting the figure "6" where appearing.

That By-law No. 45 be deleted and the following By-law shall be substituted therefor:

There shall be appointed or elected at the first meeting of the Central Council following its own election an Executive Committee which shall consist of the President, the Vice-president, the immediate Past-president, the Chairman of the Central Council (if elected), the Honorary Treasurer, the Honorary Secretary, and not less than fifteen other members of the Central Council following its own annual election as hereinbefore provided. The quorum of the Executive Committee shall be five.

That By-law No. 48 be deleted, and the following shall be substituted therefor:

The President, the Vice-president, the immediate Past-president of the Union, the Chairman of the Central Council (if elected), the Honorary Secretary, and the Honorary Treasurer shall *ex officio* be members of all Committees of the Central Council.

The following additional By-law shall be made:

Notices of Motion for the Central Council must be in writing and must be signed by a proposer and seconder, and must reach the Secretary not later than sixteen days before a meeting of the Central Council. Such notices should state whether same are made (*a*) on behalf of the Branch, (*b*) on behalf of the Group, or (*c*) on behalf of individual members.

The Ministry of Health states that the disqualification imposed by Section 42 (8) of the National Health Service Act, 1946, on Mr. D. T. Williams, dental practitioner, of Ilford, Essex, has been terminated, and that he is now entitled to participate in the National Health Service.

Association Notices

NATHANIEL BISHOP HARMAN PRIZE

The Council of the British Medical Association is prepared to consider the award of the Nathaniel Bishop Harman Prize in the year 1950. The value of the prize is approximately £100. The purpose of the prize is the promotion of systematic observation and research among consultant members of the staffs of hospitals who are not attached to recognized medical schools. It will be awarded for the best essay submitted in open competition. The work submitted must include personal observations and experiences collected by the candidate in the course of his practice. A high order of excellence will be required. No study or essay that has been previously published in the medical press or elsewhere will be considered eligible for the prize.

Any registered medical practitioner who is a consultant member of the staff or senior hospital medical officer of a hospital in Great Britain or N. Ireland and is not attached to a recognized medical school is eligible to compete. If any question arises in reference to the eligibility of a candidate or the admissibility of his essay the decision of the Council shall be final.

Should the Council of the Association decide that no essay submitted is of sufficient merit, the prize will not be awarded in 1950 but will be offered again the year next following this decision, and in this event the money value of the prize on the occasion in question shall be such proportion of the accumulated income as the Council shall determine.

The writer of the prize-winning essay may be required to prepare a paper on the subject for publication in the *British Medical Journal* or for presentation to the appropriate Section of the Annual Meeting of the Association. Each essay must be typewritten or printed in the English language, and must be distinguished by a title and a motto. The essay must not bear the name of the writer, which should be sent with the essay in a sealed envelope bearing only the motto on the outside.

The title of the proposed essay and the motto should also be notified in writing to the Secretary by December 1, 1949, on a form to be obtained from the Secretary. Essays must be forwarded to reach the Secretary, British Medical Association, B.M.A. House, Tavistock Square, London, W.C.1, not later than March 31, 1950. The prize will be awarded at the Annual Meeting of the Association to be held in 1950. Inquiries relative to the prize should be addressed to the Secretary.

RADIOLOGISTS GROUP

A meeting of the Radiologists Group will be held at B.M.A. House on Thursday, November 17, 1949, at 1.30 p.m. It is hoped that as many members of the Group as possible will attend the meeting.

LANCASHIRE AND CHESHIRE BRANCHES

The names of the two new Branches in Lancashire and Cheshire which, with the Merseyside Branch, will replace the old Lancashire and Cheshire Branch will be decided by the Branches themselves when they are inaugurated. At a meeting in Manchester on October 6 of the old Branch Council the following titles were suggested: North Lancashire for the northern group, and South Lancashire and East Cheshire for the southern group.

Diary of Central Meetings

OCTOBER

17	Mon.	Psychological Medicine Group Committee, 2 p.m.
18	Tues.	Proprietary Medicines Committee, 11 a.m.
18	Tues.	Committee on the Association of the General Practitioner with Hospitals, 2 p.m.
18	Tues.	Building Committee, 2 p.m.
19	Wed.	Film Committee, 2.30 p.m.
20	Thurs.	Dermatologists Group Committee, 10.30 a.m.
20	Thurs.	*Maritime Subcommittee of the Private Practice Committee*, 11 a.m.
20	Thurs.	Publishing Subcommittee, 11 a.m.
20	Thurs.	Health Centres Subcommittee, 11.15 a.m.
20	Thurs.	Journal Committee, 2 p.m.
20	Thurs.	Committee *re* Salaries of Medically Qualified Teachers, etc., 2 p.m.
20	Thurs.	Maritime Subcommittee, Conference of Port Medical Officers, 2 p.m.
20	Thurs.	Occupational Health Committee, 2 p.m.
21	Fri.	Public Health Committee, 1.30 p.m.
21	Fri.	*Venereologists Group Committee*, 2.30 p.m.

Branch and Division Meetings to be Held

CAMBERWELL DIVISION.—At 134, Denmark Hill, S.E., Tuesday, October 18, 8.30 p.m., Dr. W. J. O'Donovan: "The Problems of a Modern Dermatologist."

GREENWICH AND DEPTFORD DIVISION.—At Miller Hospital, Greenwich High Road, London, S.E., Wednesday, October 19, 8.30 p.m. Dr. C. W. L. Jeanes: "The Scope of Treatment in Pulmonary Tuberculosis." Members of neighbouring Divisions are invited to attend the meeting.

KESTEVEN DIVISION.—At George Hotel, Grantham, Thursday, October 20, 8.30 p.m. Dr. D. P. Stevenson (Deputy Secretary, B.M.A.): "Current Events."

MID-HERTS DIVISION.—At Red Lion Hotel, High Street, St. Albans, Friday, October 21, 8.45 p.m. Annual general meeting. Election of officers, etc. Dr. H. I. Coombs: "Blood Groups, with Particular Reference to the Rhesus Factor."

NORTH MIDDLESEX DIVISION.—At North Middlesex County Hospital, Silver Street, Edmonton, London, N., Tuesday, October 18, 9 p.m. Dr. Mair E. Morgan Thomas: "The New Bacteriological Service of the Medical Research Council."

NORTH OF ENGLAND BRANCH.—At Royal Victoria Infirmary, Newcastle-upon-Tyne, Thursday, October 20, 7.15 p.m., clinical demonstration by Mr. H. Vernon Ingram: "Squint"; 8.45 p.m., address by Professor J. C. Spence: "Comparison of Medicine in America, Australia, and Britain."

SUNDERLAND DIVISION.—At Royal Infirmary, Sunderland, Friday, October 21, 8 p.m., address by Sir James Walton: "The Progress of Gastric Surgery in the Last Half Century."

SWANSEA DIVISION.—At Osborne Hotel, Langland, Swansea, Thursday, October 20, 7.30 p.m., annual dinner.

Meetings of Branches and Divisions

MERSEYSIDE BRANCH

The inaugural meeting of the Merseyside Branch was held at Liverpool on September 28. The following officers were elected: President, Mr. B. L. McFarland; vice-presidents, Dr. H. S. Pemberton and Mr. A. A. W. Merrick; secretary and treasurer, Dr. V. Colton Cornwall.

At the dinner which followed Professor C. A. Wells proposed the toast of the new Branch and surveyed briefly the history of the Association. The time had come, he said, for the consultants as a whole to take a fuller part in the activities of the Association and for all members of the profession in this compact Merseyside Branch and Region to speak with one voice. Mr. Bryan McFarland replied, and said that it was n[illegible] that the president of the new Branch and the [illegible] Association (Professor T. P. McMurray) were [illegible] rgeons, remarking that the National Health Service might well need some corrective treatment. Referring to the next Annual Meeting of the B.M.A. on Merseyside, he asked for the support and help of all in making it a success, stating how proud the new Branch would be that Professor McMurray was to be president.

Professor McMurray proposed the health of the Association coupled with the name of Dr. Charles Hill, its Secretary. He mentioned that when its original membership was only 310 its Council consisted of 70. Soon after the creation of the Association two members of Parliament had brought in a Bill for the regulation of the profession, and after an interrupted struggle of 26 years the first Medical Act was passed in 1858, which was the first-fruit of the work of the Association. The problem of providing a perfect health service was not finished; the organization which we had now could be improved in many ways. Faults must be eliminated and improved methods adopted. Effective measures were available, but they could be completed only with the undivided support of the whole profession. The struggle of the Association depended large on its officers.

Dr. Charles Hill replying thanked the previous speaker, and paid tribute to the contribution of the Merseyside Branch in past years, mentioning the work of men like J. C. Matthews, R. W. Kennon, and R. E. Gibbons on the Council, and Sir Henry Cohen, chairman of the Association's committees on undergraduate and postgraduate medical education. The profession had sometimes failed to realize when it had established a position, and tended to press for some other point, almost forgetting what it had achieved. The profession's unity and strength depended on its achieving right conditions of service and on the quality of the service that it gave.

TRADE UNION MEMBERSHIP

The following is a list of local authorities which are understood to require employees to be members of a trade union or other organization:

Metropolitan Borough Councils.—Fulham, Hackney, Poplar.

Non-County Borough Councils.—Dartford, Wallsend.

Urban District Councils.—Denton, Droylsden, Houghton-le-Spring, Huyton-with-Roby, Redditch (restricted to new appointments), Tyldesley.

ARTIFICIAL KIDNEY*

BY

GORDON MURRAY, M.D., F.R.C.S., F.R.C.S.Can.

EDMUND DELORME, F.R.C.S.Can.

AND

NEWELL THOMAS

Toronto, Canada

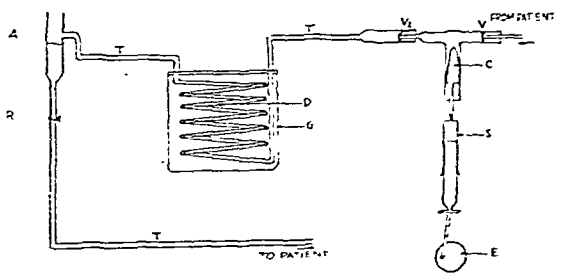
In ancient times it was thought that the kidneys were linked closely with the temperament of the individual, and physicians of old practised largely on physic and examination of the urine. With modern pathology, much more has been learned about the kidneys in many respects, but their detailed function is still a mystery.

Our interest in an artificial kidney came only as a sideline to the work being done with heparin, and fundamentally a good anticoagulant is paramount when blood is to be circulated through any system of artificial tubes.

There were other reasons which made such an investigation more or less logical. The ever-present patient with anuria, for whom so little could be done unless the kidneys themselves decided to go to work, also offered a real challenge. The persistence of anuria in a patient who may look and feel well induces in the doctor in charge a series of changing moods ending in desperation and an admission of helplessness from ignorance of the disease of uraemia, its cause, how it acts, and its cure.

With heparin as an anticoagulant, attempts were made to clear the blood stream of toxic substances by transplantation of a kidney from one animal to another and from one species to another. This work was done in 1933–5 with moderate success (Murray, Delorme, and Thomas, 1947). The objective in this present investigation was to produce similar effects by preventing a patient from dying of acute toxaemia in such conditions as acute mercury and phenol poisoning, in the toxaemias of acute infections such as nephritis or pneumonia, etc., with oliguria or anuria, as well as in acute anurias following blood transfusions, crush, excessive sulpha-drug administration, eclampsia and toxaemia of pregnancy, severe skin burns, induced abortions, acute injury to ureters and kidneys from calculus obstructions, reflex or otherwise, or following operation. This thesis is supported by Trueta's (1947) work, in which it was shown that the cortex of the kidney may be put out of action by various reflex or other means, and that it may regain its function provided the patient survives long enough.

It therefore seemed possible, if the patient could be protected from death from toxaemia in such conditions, that after a time a number of the kidneys affected might recover enough to resume function, and such has been the case in several instances.



It was with satisfaction, therefore, that experimental results to justify this thesis were noted and also that clinical evidence has supported the claim. Also, it has been demonstrated repeatedly that the apparatus works smoothly for long periods, and that it performs the functions for which it was developed.

Many workers, including Abel, Rowntree, and Turner (1913, 1914), Thalhimer (1938), and numerous others, have embarked on similar investigations, but the work has not to our knowledge been developed to a point where it was a proved effective clinical method of treatment. The one exception is that of Kolff and Van Noordwijk (1946), in Holland. We were not aware of their investigations, and not until after the war did we hear of their results. Their excellent monograph gives evidence of the treatment of an extensive series of patients, with some good clinical results. Apparently our efforts have been carried on simultaneously, and they were quite independent. It was interesting, therefore, to compare the methods and the material used, and to note the different avenues followed, which evidently converged fairly closely towards the same goal of end-results.

Development of the Apparatus

The principles of our artificial kidney are: (1) a dialysing membrane which is selective in allowing the passage of some substances and not of others from the blood stream—namely, non-protein nitrogen and other toxic substances. (2) a method of circulating the blood through this extrinsic system; (3) protection from removal of necessary substances from the blood stream.

It was not until very extensive and arduous trials and experiments had been made that we finally arrived at the present set-up (see Diagram), which works satisfactorily both experimentally and in clinical patients.

Schematic diagram of artificial kidney (not drawn to scale). V, and V₁ = valves. C = condom. S = syringe E = eccentric. T = rubber tubing. A = air trap. R = inlet control. D = dialysing membrane. G = Bath jar.

*Based on the Alexander Simpson-Smith Lecture delivered at the Hospital for Sick Children, Great Ormond Street, on July 11 by Dr. Gordon Murray.

The following is a summary of some of the series of events which led to the development of the apparatus and of what might be termed the evolution of this instrument.

1. The first method was the circulation of arterial blood with return through the venous side through several coils of cellulose acetate tubing (sausage-casing) bathed in warm tap-water. This tubing was 1 in. (2.5 cm.) in diameter and presented the primary disadvantage of the volume/surface-area ratio. Also, the size of the tubing allowed escape of too much of the animal's blood before there was sufficient return, if a reasonable length of it was used. In this way the animal really had haemorrhage into the tubing. Filling this with blood beforehand overcame the difficulty.

2. Later on, with considerable effort, tubing ½-in. (1.25 cm.) in diameter was obtained, with somewhat better results. Then ¼-in. (0.6-cm.) tubing was obtained from the Visking Corporation, of Chicago, and this gave fairly satisfactory results.

3. With sufficiently long sections of this tubing *in vitro* we were able to demonstrate that there was some passage of N.P.N. substances through this membrane and that the larger protein molecules did not pass (Chart 1).

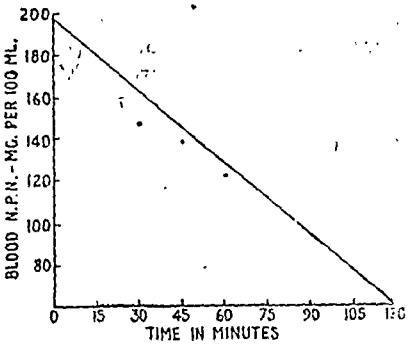


Chart 1.—Showing dialysis of N.P.N. from human blood *in vitro*. 2.3 g. of N.P.N. was removed in two hours. No proteins came through.

4. To diminish the volume of these tubes, it was attempted at first to pass the tubing through a series of wire cells containing the dialysing tubes.

5. Next, concentric wire cylinders between which the tubes were partly compressed were used.

6. Then we tried a wooden reel on which the coils could be assembled fairly quickly. This did not control the volume satisfactorily.

7. Next it was decided to coil the tube round a small platform, when plastic perforated sheets were applied on each side and bolted together to compress the tubing in the coil. These were found to be unsuitable because of the bulging under the pressure of the fluid in the coil.

8. Then sheets of the plastic plates were replaced by wood, and these were found to warp.

9. The latter were replaced by aluminium-steel plates, which were bolted together with a thin definite spacing between them. This worked moderately well, but was finally discarded for

10. A vertical wire-mesh cylinder around which the tube was wound in spiral fashion and held in place by cross-pieces of wood. This method finally gave the best result with the ¼-in. tubing, and lengths up to 150 ft. (45.72 metres) of tubing could be used quite satisfactorily, giving a fairly high rate of dialysis.

Sources of the Blood for Dialysis

The next problem to be solved was that of a method of circulating the blood. Early on it was decided that using an artery as the propelling force had many disadvantages: (1) The artery could be used only once; if further attempts were to be made another vessel would be required. (2) The pressure in the system was such that there was not a satisfactory return of the venous blood by this type of pressure. Moreover, the animal tended to act as from the result of haemorrhage from the arterial bleeding.

In all these methods, of course, it is quite obvious that the animal was highly heparinized to make sure that there was no clotting or thrombosis either in the system or at the points of intake or output or in the animal itself.

It was decided to attempt to develop a method by which the blood could be taken from the venous system and then returned to it through another point. On this basis, blood was taken first from femoral veins, then from external jugular veins, but it was found that with any pump system which produced suction the vessel collapsed and acted as a valve over the tube. To overcome this difficulty a catheter of fairly large diameter was finally passed through the femoral vessels and into the inferior vena cava or into the right heart region. From this any quantity of blood could be removed by aspiration without any interference or obstruction, and it could be returned quite readily to a vein on the opposite side. This seemed to have many advantages: (1) there was no ill effect on the animal's pressure simulating haemorrhage; (2) the quantity of blood removed could be controlled accurately, which was not the case when an artery was used; (3) the venous blood, unoxygenated, was circulated through the system, and therefore more impurities were available for dialysis by this method; (4) the blood was not oxygenated, and, as well as dialysing it, it was easy to add oxygen during the circulation through the system of tubes.

Pump System

The next problem was one of providing a circulating pump system which would not damage or crush the blood corpuscles, would not produce haemolysis, would work smoothly, and would not become plugged and clotted with fibrin. At first the blood was drawn into a flask, circulated through the dialyser, and then returned to the venous system by gravity.

Next a piston syringe was used as a pump, with intake and outlet valves on glass seats, but it was early demonstrated that in spite of high heparinization the spinning of these valves and the passage of the blood through the small apertures tended to cause some collection of fibrin and to interfere with the functioning of the system. In place of this a rotary-pump effect was used, but it was only moderately satisfactory. Finally, a pump system was used whereby a rubber tambour was inflated and deflated by the action of the piston syringe attached to an electric motor. Rubber intake and outlet valves gave good results, so that a smooth circulation, without injury to blood and without clotting and deposit of fibrin or platelets, could be ensured for many hours at a stretch.

Experiments on Increasing Dialysis

Many efforts were made to increase the rate of dialysis through the membrane.

1. The best and most obvious means was by increasing the length of the tubing used. Lengths up to 35 ft. (10.67 metres) were employed quite satisfactorily, and it is possible that this length could be considerably increased with still more beneficial effect. Recently lengths of 150 ft. (45.72 metres) have been used.

2. It was thought that by attempting to reduce the atmospheric pressure surrounding the tubing an improvement in dialysis might be obtained, but the results were not very satisfactory.

3. By increasing the pressure within the dialysing tubing it was hoped that there might be some increase in the dialysis, but again this requires further study to be certain of the effect.

4. Some investigation was carried out to see if the work described by McBain and Kistler (1928, 1929, 1930, 1931) would apply under these conditions. These authors indicated that the use of 64% zinc chloride solution would stabilize the apertures in the membrane and increase the rate of dialysis. Extensive tests, covering several months, were done with this. It was our conclusion that, while there was some benefit in the rate of dialysis early in the exchange, in the final results there was not a very great difference. The difference did not seem to be great enough to justify the effort and trouble of treating the tubing, and for that reason the method was discarded and the untreated tubing was used. It was noted in our experiments

that the use of zinc chloride, with adequate washing afterwards, did not seem to produce any toxic effects in the animal.

The Dialysate

The next problem, related to the protection of the animal against the removal of substances which are necessary for life, involved a great deal of work and was the most difficult to solve.

If an animal's blood was dialysed through this instrument *with a surrounding bath of tap-water it was found that* within five to seven minutes the animal showed very striking clinical changes. The rate of breathing was accelerated until this became very violent. There was shock and collapse, and the animal died within a period of seven to fifteen minutes.

At this stage we were not certain whether important substances such as adrenaline, "pituitrin," insulin, heparin, and so on were being removed and whether the animals were going into shock on this account. As the chemical tests for some of these substances are exceedingly difficult and uncertain, we were not convinced by chemical analysis whether such was the case or not. However, we arrived at our final conclusions by the following methods:

During dialysis it was demonstrated that the animal had an increasing concentration of haemoglobin, and that it showed evidence of water loss. It was therefore decided to balance the dialysate surrounding the tubing with some of the normal substances in blood as indicated in Ringer's solution. It was found that by an addition serially of each one of these substances we could overcome one or other of the difficulties and could carry on a dialysis without producing these disastrous effects on the animal. When the chlorides, the calcium, the magnesium, the potassium, the sodium, the phosphate, the carbonate, and the sugar were balanced in turn these disastrous effects did not occur. In the preparation of our dialysate it was found that with the potassium left out the animal suffered ill effects and when potassium was added it was protected against these effects, and similarly with the other salts and sugar. Variations in the *p*H also caused alarming results. It was necessary to add bicarbonate to the solution so as to maintain the *p*H at a level of about 7.3. With the dialysate at this level there was no change in the blood *p*H during or following dialysis.

However, as both quantitative and qualitative tests for some of these chemicals are difficult and unreliable, we found it difficult or impossible to prove the specific effect of the lack of potassium, calcium, etc., although the experimental proof of this seemed to be adequate. Finally, a bath solution similar to that used by Seligman, Fine, and Frank (1946) was used. It contained sodium chloride, calcium chloride, magnesium chloride, potassium chloride, sodium hypophosphate, sodium bicarbonate, and dextrose in physiological amounts. This solution was well buffered, but a certain care in mixing and autoclaving was required to prevent precipitation of insoluble salts.

Transfusion of Blood

The next problem was the fact that in a smallish or medium-sized animal there was so much loss of blood into this machine before any was returned that the animal was left with saline in its circulating system and all its blood out in the apparatus. However, this was overcome by filling the machine with suitable blood for the animal. When this was done the circulation could be carried on indefinitely without ill effects.

Many of our earlier experiments were carried out *in vitro* by circulating blood and other solutions through the instrument and by placing substances in the circulating fluid which could be detected in the surrounding dialysate. Next, in a normal animal, with the circulation going, 5 g. of urea was injected and the rate or removal of this was determined. With the tendency of urea to form a closer relation in the blood of the dog, it was probably not as fair a test of dialysis as might occur in the human being, in whom the urea is separated more readily and is more easily dialysable. However, this did demonstrate the rate of removal of N.P.N. substances from a normal animal.

Uraemia in Animals

The next problem was to produce azotaemia in an animal so that the effectiveness of the apparatus could be assessed under these conditions. Bilateral nephrectomy was found to involve a number of uncontrollable factors, and the uraemia so produced was so severe and was associated with such a poor resistance in the animal that it did not lend itself to these experiments. A more gradual onset of uraemia was desirable, and was thought to be more comparable to the clinical condition in patients.

The chemical production of oliguria and anuria was investigated, but no completely selective uncomplicating poison which seemed suitable was encountered. Most of the work done on specific kidney damage involved the perfusion of the kidney by exposure and cannulization of renal vessels.

Ligation of ureters was performed on a series of animals, but sudden death, presumably from cardiac arrest, as has been described in the literature, was so frequent before dialysation could be carried out that many of the animals succumbed. Finally, an interesting method of producing uraemia was employed. The ureters were transplanted into the small bowel in the hope that there would be enough resorption of non-protein-nitrogen bodies to produce uraemia. This took place in a surprisingly short time, and high levels were reached in three or four days, associated with lethargy and diarrhoea. The animals, however, maintained their food and fluid intake, which was not the case with nephrectomized animals or in those with ligated ureters.

The study showed that blood may be circulated outside the body, and that with a reasonable length of dialysing tubing moderate amounts of N.P.N. can be removed in short periods from normal and uraemic animals, provided these animals are not moribund or in a state of severe circulatory depression. The N.P.N. level in the blood varies greatly in the above state and is a less reliable guide to the efficiency of the dialysation than is the N.P.N. measurable in the dialysate removed during the test run.

It seemed obvious from the experiments as well as from the effects on patients clinically that the level of N.P.N. substances measured in the blood gave only a poor indication of the effect of such dialysis. Obviously the N.P.N. substances in the blood stream are not produced there, but are the waste products delivered to this circulating medium from the tissues in which they are formed. This circulating medium, the blood, has the function of carrying these substances to points where they are detoxified and prepared for excretion, and finally are carried to the kidney, where they are excreted from the system. While the level of N.P.N. substances in the blood may be reduced somewhat, the essential point in treatment is to reduce these and other toxic substances in the vital centres and other fixed tissues. During many of the experiments and in the clinical runs more N.P.N. was removed than was contained in the total volume of blood in the animal and still the level in the blood stream was lowered only slightly. Thus it was obvious that there is a constant drainage of these substances from fixed tissues into the blood stream, one of whose functions is to transport the substances for disposal.

It seemed of interest to investigate this aspect of the problem. For that purpose animals were nephrectomized and the N.P.N. of the blood and spinal fluid was followed as the animal developed uraemia. When the N.P.N. had reached a high level in these two fluids the animal was sacrificed and blocks of tissue were immediately frozen, ground up, and N.P.N. estimations done on these by Dr. Gornall. Chart 2 indicates the state of affairs here. When

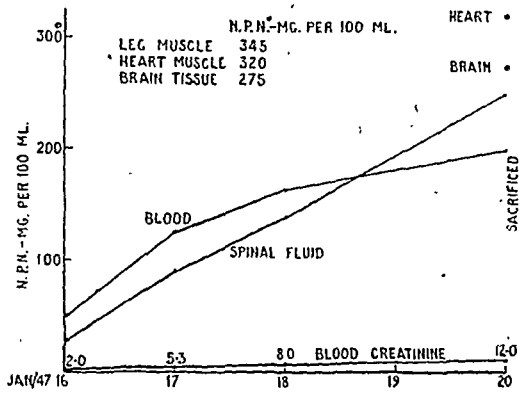

CHART 2.—N.P.N. levels in a male dog weighing 12 kg. after left nephrectomy and ligation of right ureter.

the blood N.P.N. reaches a certain level the spinal fluid level is above this, and the level of the N.P.N. substances in the tissue examined was above that level again. This would tend to bear out the point already made that the blood is only a medium for the collection of these substances and washing away of them for disposal.

When, therefore, in a clinical patient it was reported that 12.97 g. of N.P.N. substances was removed and readings of the blood showed only a slight depression of the N.P.N. level it was obvious that the N.P.N. substance removed was bringing down the level of these toxic substances in the vital fixed tissues of the patient, and the proof of this was the clinical improvement, with diminishing signs of toxaemia, even though the blood N.P.N. was still at a fairly high level.

From the events observed in animals and clinically, we think it can be assumed with fair certainty that, while N.P.N. substances can be removed, there are other substances that are also removed by this dialysing system. These substances are probably responsible in large part for the severe toxaemia and ultimately for death. Proof of this is the fact that in a normal animal from four to ten times the amount of urea necessary to place the N.P.N. at a high level can be given without much injurious effect. Probably, therefore, another substance is responsible for the toxaemia. This substance has not yet been separated and has not been described or analysed, but this system offers an excellent method of approach to the study of such substances, as suggested by Abel, Rowntree, and Turner (1913, 1914).

This work represents some early excursions into a field which offers great prospects for expansion. The method might be used therapeutically to remove toxic substances as well as to administer substances which may be beneficial for the individual.

Several tests have been made on patients to assess the functioning of the apparatus. The cases reported illustrate the ability of this apparatus to perform what was intended

Case 1

The patient, a woman aged 26, had anuria for a period of nine days after an attempt at induced abortion. During these nine days she was passing about 35 ml. of urine daily, and when first seen was in a state of uraemia. She was comatose, was having mild uraemic convulsions, was severely oedematous, and was not passing urine. She was seen by the physicians, the gynaecologists and the genito-urologists, all of whom agreed that her case was utterly hopeless; in fact, they had given up treatment except for some diathermy which was being applied through the loins.

On the ninth day the patient was attached to this artificial kidney by passing a catheter through the saphenous vein into the inferior vena cava on the right side, and another into the femoral vein on the left. With the machine running for one hour she was moderately improved. The results of the run are shown in Chart 3.

Towards the end of the hour the patient showed some discomfort. She developed a fairly severe chill. Because of this and not knowing just what the effects were, and because of difficulty in following the chemistry accurately, the dialysis was discontinued at the end of an hour. It was shown fairly conclusively on subsequent runs without any similar ill effects that the probable trouble was inadequate washing of the tubing. On all occasions we used new tubing throughout, including rubber tubing, the tambour in the pump, and the dialysing membrane. On the subsequent occasions this was thoroughly washed through with distilled water for an adequate period of time and then washed for a short time with blood solution to remove any remaining substances either in the dialysing membrane or in the tubing. On subsequent runs lasting up to eight hours there were no ill effects whatever in the form of thermal reactions, changes in respiration, pulse rate, blood pressure, or otherwise.

Following the treatment the patient was considerably improved clinically. The next day her condition was fair.

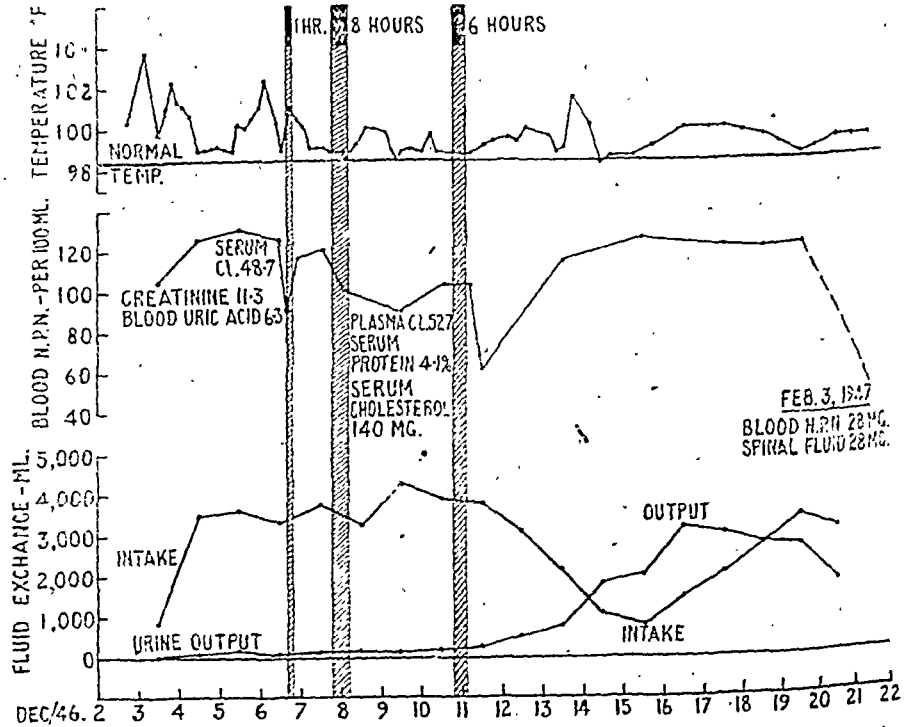

CHART 3.—Case 1. The shaded columns on the sixth, eighth, and eleventh days show the period of dialysis with the artificial kidney. The fall to normal of the blood N.P.N. on February 3 is indicated.

The day after that she was much worse again and another run of eight hours was given on the machine. The results of this are shown in Chart 3. Her condition was very greatly improved. There was still only 45 ml. of urine. Three days later the patient's condition was again serious and another run of six hours was given. The clinical improvement of the patient was very striking. She was comatose at the beginning of each one of these runs on the machine; at the end she was quite bright. The delirium and coma had disappeared. The patient would drink small quantities of fluid, would respond to questions and conversation, and stated that she felt much better. In spite of the pronounced oedema there was some appearance of intelligence in her face.

During the runs on the machine samples of blood, ascitic fluid from the peritoneal cavity, and spinal fluid were removed, and N.P.N. and other tests done on these.

After the last dialysis there was a moderate secretion of urine, and next day there was an enormous secretion of 4,000 ml. of urine. Subsequently the patient made a progressive and uninterrupted recovery and returned to normal health. During the next two weeks samples of both blood and spinal fluid showed a progressive fall of N.P.N., until on the twenty-fifth day these had both reached normal. The oedema had entirely disappeared. The patient was up and about, and was in normal health. At this stage the gynaecologists reported that the foetus was not present in the uterus. While there was no record of its escape, I think one cannot assume that the dialysing apparatus removed it by this means. The patient was in hospital 33 days.

The only remaining abnormality was a lack of concentration on the two-hour test. The urinalysis otherwise was quite normal and the two-hour test showed a concentration only up to 1012. However, as shown on the final point on Chart 4,

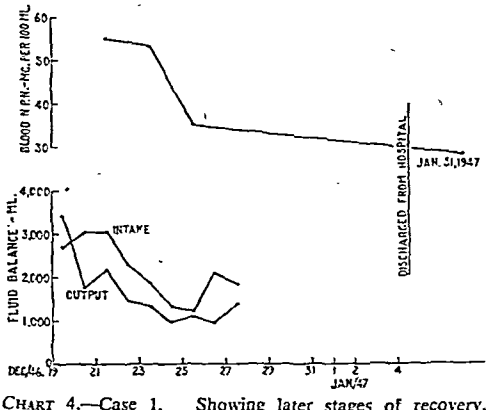

CHART 4.—Case 1. Showing later stages of recovery. N.P.N. and water balance returned to normal.

on the sixty-first day the blood N.P.N. was 28 mg. per 100 ml. The spinal fluid N.P.N. was also 28 mg. per 100 ml., and the two-hour test showed considerable improvement. Here the concentration went up to 1018, and the day and night quantities were fairly normal. The patient has gone back to her regular work and is in normal health. She has since married and given birth to a normal child. Kidney function was watched closely throughout pregnancy, and at no time was there evidence of toxaemia or impaired function.

Case 2

A married woman aged 40 was seen by the courtesy of Dr. J. Crosbie. After caesarean section, when a blood transfusion was given, there was oliguria, and the urine contained haemoglobin and haematin. She passed only 3 to 5 ml. of urine daily for eight days, at which time the blood N.P.N. was 179 mg. per 100 ml. and the patient was showing signs of uraemia.

She was then treated for 26 hours with the artificial kidney. Fifty-four feet (16.5 metres) of tubing was used and 70 g. of N.P.N. was removed from the blood. The following day the urinary secretion increased to 210 ml., rising to 6,730 ml. on the fifth day. The patient gradually improved, and has made an excellent recovery. Renal function has returned to normal and she is in normal health.

There has been survival in about 50% of the patients treated. Those who succumbed were found on the whole to have had chronic kidney disease, and even though the purification of the blood was accomplished satisfactorily they relapsed into a uraemic state.

We wish to thank Professor Van Wyke and Professor J. McClelland for providing some of the patients. We acknowledge with thanks the privilege of laboratory space and the use of some chemicals provided by Professor Andrew Hunter. The assistance of Dr. Allan G. Gornall in doing N.P.N. assays of tissues is acknowledged with thanks. Otherwise the work was carried on independently of the University or other assistance.

MALARIA

WITH SPECIAL REFERENCE TO CERTAIN EXPERIMENTAL, CLINICAL, AND CHEMOTHERAPEUTIC INVESTIGATIONS*

BY

N. HAMILTON FAIRLEY, C.B.E., M.D., D.Sc. F.R.C.P., F.R.S.

Wellcome Professor of Tropical Medicine, London School of Hygiene and Tropical Medicine; Physician, Hospital for Tropical Diseases, University College Hospital, London

LECTURE II: CHEMOTHERAPY

The factors which may modify the results obtained by treatment with antimalarial drugs include not only the species of the malaria parasite but the variety or strain of the particular plasmodium implicated. The presence or absence of immunity or partial immunity in the patient is very important, and racial considerations may be relevant. Those of negroid stock are sometimes relatively refractory to infection, while Caucasians show maximum susceptibility.

Regarding strains of parasite, James (1931) reported that the Rome strain required eight times as much quinine as the Indian strain of *P. falciparum* to elicit a satisfactory therapeutic response; both strains were equally susceptible to "atebrin" (mepacrine). The Madagascar strain of *P. vivax* was twice as susceptible to "neosalvarsan" (neoarsphenamine) as the local Dutch strain.

Variations in the sensitivity of different strains of the same species of parasite to a given antimalarial drug illustrate the inadvisability of assuming that because a drug in a certain dosage is effective in one geographical area it will necessarily be equally so in another. This point will be specifically illustrated later with reference to mepacrine and proguanil in New Guinea strains of *P. falciparum*.

*Second of the Croonian Lectures delivered at the Royal College of Physicians of London on May 3 and 5, 1949.

The antimalarial drug or combination of drugs used may vary according to the stage, or stages, of the life cycle of the parasite on which the chemotherapeutic attack is made —i.e., the pre-erythrocytic cycle, the asexual blood parasites, the late exo-erythrocytic forms, or the gametocytes.

Prevention and Suppression of Malaria by Chemotherapy

Precise knowledge regarding the suppressive and prophylactic value of antimalarial drugs in non-immunes was very unsatisfactory at the outbreak of hostilities in 1939. The entry of Japan into the war in November, 1941, found the Allies unprepared for warfare in tropical climates and especially for using their non-immune troops in hyperendemic areas of malaria. Malaria casualties in the South-West Pacific and South-East Asia in 1942 were very grave. Some 90% of the forces operating in the Solomons and New Guinea developed severe malaria within four months, and in all these campaigns the type of malaria breakdown was constant. Malignant tertian malaria was responsible for approximately 80–90% of overt attacks during actual jungle fighting, the remaining 10–20% being caused by benign tertian malaria. Later, after a full course of quinine–mepacrine–pamaquin therapy, troops relapsed predominantly with benign tertian malaria, recrudescences of falciparum malaria being uncommon provided reinfection had not taken place.

The malaria problem was one of great gravity, and Allied military and medical authorities decided that every possible channel should be explored to increase the effectiveness of the control of malaria in the forward areas, and that special efforts should be made to discover more potent antimalarial drugs for its control and prevention in jungle warfare. In this connexion a large medical research unit was established at Cairns, in Northern Australia, for the specific purpose of investigating the effectiveness of various antimalarial drugs in experimentally infected Australian Army volunteers living in the Tropics and tested under conditions simulating jungle warfare. During these researches some 850 healthy volunteers were experimentally infected with sporozoite-induced malaria, using strains of *P. falciparum* and *P. vivax* from New Guinea and New Britain. Despite intense hyperinfection none of these volunteers died from malaria, and though subinoculation was practised on a scale never previously attempted no ill effects were noted. The subinoculation technique adopted by Fairley (1945) and Fairley *et al.* (1946a, 1947) afforded data which enabled antimalarial drugs to be classified into one of two groups:

1. *Schizonticidal suppressants*—i.e., those which exerted suppressive and possibly curative effects by schizonticidal action after asexual parasites had appeared in the blood. The drugs which were found to produce suppression of malaria by schizonticidal action on the asexual erythrocytic parasites included quinine, sulphadiazine and allied drugs, mepacrine, "sontochin," and "chloroquine." While taking an effective suppressant dose of these drugs each day, subinoculation of 200 ml. of blood collected on the seventh day after exposure of the donor to infection with *P. falciparum* and on the ninth day with *P. vivax* invariably led to malaria in the recipient, showing that suppression was achieved by schizonticidal action and not by its effects on pre-erythrocytic forms of the parasite.

2. *Causal prophylactics*—i.e., those which acted on sporozoites or pre-erythrocytic forms, either destroying them before they gave rise to asexual erythrocytic parasites (complete causal prophylaxis) or temporarily inhibiting or modifying their schizogonous cycle so that the appearance of asexual erythrocytic parasites in the circulating blood was delayed and the incubation period prolonged (partial causal prophylaxis). Subinoculations made on the seventh day in *P. falciparum* infections and on the ninth day in *P. vivax* infections were invariably negative. Only the biguanides or the 8-amino-quinolines fall into this category. As all the more important antimalarial drugs were tested at Cairns for suppressive and prophylactic purposes under experimental conditions not available elsewhere, my remarks on the control of malaria by chemotherapy will largely be based on these researches.

1. Schizonticidal Suppressants

Quinine

Quinine sulphate in a dosage of 10 gr. (0.65 g.) daily proved ineffective as a suppressant against malaria resulting from mosquito-transmitted New Guinea strains of *P. vivax* and *P. falciparum*. When the daily dose was increased to 20–30 gr. (1.3–2 g.) suppression was complete; radical cure resulted in falciparum malaria provided this dosage was continued for 23 days after exposure, though not in vivax malaria. With this high dosage parasites were not demonstrated in thick smears, but subinoculations were positive on the seventh day in malignant tertian infections, showing that radical cure was obtained by schizonticidal action, not by a causal prophylactic effect.

As 10 gr. of quinine approximated to the maximum daily dose that could generally be tolerated for any prolonged period, it was evident that quinine was unsuitable for suppressive purposes in the South-West Pacific. With certain Indian and African strains of *P. falciparum* and *P. vivax* a daily dose of even 5 gr. (0.32 g.) of quinine effectively suppresses malaria, but after medication ceases overt malignant tertian and benign tertian malaria develop.

The great drawback to quinine as a suppressive drug is that it so often fails to produce radical cure of malignant tertian malaria in the usual suppressive dosage and leads to a condition of chronic latent or chronic recrudescing malignant tertian malaria, in the presence of which true blackwater fever is apt to develop. For this reason, if for no other, quinine is unsuitable for suppressive purposes in Europeans. Blackwater fever practically disappeared from New Guinea and elsewhere in the South-West Pacific with the radical cure of malignant tertian malaria in the early stages of the infection. This was occasioned by the introduction of mepacrine for suppressive purposes and for the treatment of the clinical attack. A similar result was recorded by Findlay and Stevenson (1944) in West Africa.

Sulphonamides

Coatney and Cooper (1948) record that prophylactic action against gallinaceum malaria in birds has been demonstrated for over 30 sulphonamide derivatives since they established early in 1942 that sulphadiazine would prevent this infection (Coatney and Cooper, 1944). Several years earlier "proseptasine" in large dosage had been reported to have true prophylactic action against *P. falciparum* by Sinton, Hutton, and Shute (1939), and late in 1942 high hopes existed in the U.S.A. that sulphamerazine would prove a true causal prophylactic for human species of malaria parasites. In 1943 supplies of sulphamerazine were sent from the U.S.A., and that drug, along with sulphadiazine and sulphamezathine, was fully investigated by Fairley (1945) for prophylactic action in human malaria, unfortunately with disappointing results.

In vivax malaria all these drugs proved ineffective suppressants of both trophozoite and sporozoite experimentally induced infections, even in a dosage of 1 g. daily. In falciparum malaria they proved good suppressants and generally brought about radical cure. Though parasites were rarely demonstrable in thick blood smears, subinoculations on the seventh day after exposure to infection were

positive—a result which showed they were not true causal prophylactics in man. Owing to their failure to suppress vivax infections and because of toxic effects such as agranulocytosis, it was decided that these sulphonamides should not be used in the South-West Pacific for malaria suppression.

Using sulphadiazine and sulphapyrazine, Coatney *et al.* (1947a, 1947b) reported similar experimental findings in volunteers infected with the McLendon strain of *P. falciparum* and the St. Elizabeth strain of *P. vivax*.

Mepacrine ("Atebrin")

Though the dosage of mepacrine advised in the South-West Pacific had been one tablet daily (0.1 g.), malaria casualties in the Huon Peninsula campaign in 1943 were devastating. The ratio of medical : battle casualties was 15 : 1; malaria constituted over 60% of the medical casualties. There was definite evidence that mepacrine discipline was poor and that the drug was not being regularly taken.

Later in the same year excellent results were obtained in volunteers at Cairns receiving one tablet (0.1 g.) of mepacrine on six or seven days of the week for four weeks before exposure to infection, during the period of exposure, and for 23 days after the last infective bite (New Guinea strains). Controls not taking the drug, who were bitten by the same number of infective mosquitoes from the same batch, invariably developed malaria.

1. *Benign Tertian Malaria.*—Though volunteers infected with *P. vivax* did not develop attacks of overt malaria when receiving mepacrine in the above dosage, overt malaria developed two to seven weeks after stopping the drug.

2. *Malignant Tertian Malaria.*—Volunteers repeatedly exposed to 10 to 20 infective bites (*P. falciparum*) failed to develop overt malaria when following an identical suppressive mepacrine regimen. Mild clinical features associated with slight transient rises in temperature, fleeting aches and pains, and perhaps some tenderness or temporary enlargement of the liver and spleen were sometimes noted, but symptoms were never severe enough to necessitate rest in bed, and the volunteers invariably carried on their routine activities. Despite these minor symptoms parasites were rarely, if ever, demonstrable in thick blood films during exposure to infection while taking mepacrine, though subinoculations might be positive. After cessation of the drug overt malaria failed to develop, subinoculations were negative, and on superinfection volunteers showed normal susceptibility—i.e., they developed overt malaria when they were reinoculated with blood containing the same strain of *P. falciparum*. These findings constituted a chain of evidence indicating that malaria infection had been either prevented or cured. Early subinoculation from the seventh to the 11th day after infection or reinfection, however, had revealed parasites in the blood even though they could not be demonstrated microscopically. It was therefore evident that in malignant tertian malaria mepacrine was not acting as a causal prophylactic, but was producing radical cure by schizonticidal action, destroying the young asexual parasites after they had gained access to the circulation.

3. *Mixed Infections with P. falciparum and P. vivax.*—In jungle warfare troops were generally infected with both *P. falciparum* and *P. vivax*. To reproduce field conditions experimentally it was necessary to infect volunteers repeatedly over a period of several months by exposure to vivax- and falciparum-infected mosquitoes. In addition it was essential to subject these volunteers to conditions generally believed to favour malaria relapses, such as physical fatigue, cold, anoxia, blood loss, etc.; all this was done, but in no instance did overt malaria develop while they were taking mepacrine. On an average of 30 days after cessation of mepacrine, volunteers developed overt benign tertian malaria; falciparum parasites, however, were not found.

These experiments were of considerable significance from a military point of view. They indicated that where similar strains of *P. falciparum* abounded troops could fight in hyperendemic areas of malaria without significant malaria casualties provided they were taking mepacrine in adequate daily dosage: in addition they implied that there should be no deaths, no malaria carriers, and no blackwater fever if the daily dose was continued for three to four weeks after leaving the endemic area. After stopping mepacrine, however, troops infected with suppressed vivax malaria would develop overt attacks.

Following receipt of the results of these experiments, military disciplinary measures in regard to mepacrine administration were widely enforced. Malaria casualties rapidly diminished and the experimental findings were confirmed in jungle warfare throughout the South-West Pacific except in 1945 in the limited Itape-Wewak area, on the northern coastline of New Guinea, where moderately severe malaria casualties occurred. Fairley *et al.* (1946b) found that in addition to the universal mepacrine-sensitive strain a relatively insensitive strain of *P. falciparum* was present in troops there which required 0.2 g. daily for its certain suppression and larger doses than usual for therapeutic purposes.

In volunteers infected with the ordinary New Guinea strains the mean plasma mepacrine level of over 20 μg. per litre was found adequate to suppress either vivax or falciparum infections. With the atypical Itape-Wewak strain which was relatively insensitive to mepacrine breakthroughs occurred in volunteers when the plasma mepacrine level was well above 30 μg. per litre. This strain showed no decreased susceptibility to chloroquine or proguanil, and if either of these drugs had been available it could have been substituted in the usual dosage for mepacrine with certainty of success. Bang *et al.* (1946a), as a result of studies on the efficiency of mepacrine suppression in the South-West Pacific, concluded that it was mainly a problem of drug administration and that clinical malaria developed in the presence of inadequate amounts of mepacrine. The concentration of mepacrine present in break-throughs was the same in chronic relapses and primary attacks of malaria. They considered there was no need for a dosage greater than 0.1 g. per day. They also found that in at least 98% of the American troops in strenuous combat who received 1 g. of mepacrine per week (generally in bi-weekly doses of 0.5 g. each) malaria was fully suppressed (Bang *et al.*, 1946b).

The 4-amino-quinolines

Sontochin and chloroquine ("resochin") belong to the 4-amino-quinoline group of compounds which were synthesized by German chemists in 1934 and patented in 1939. They had not then been subjected to extensive biological testing and their clinical study was being attempted by the French at the time of the invasion of North Africa, when sontochin fell into Allied hands. These drugs and others of the group were resynthesized in U.S.A. and tested biologically on a large scale in both bird malaria and man in 1943–4, when they were sent to the Cairns unit to be investigated as suppressants and causal prophylactics. Detailed results, which were summarized by Fairley (1946), were communicated to the National Medical Research Council, U.S.A., in 1944.

The suppressive dosage used was 50–100 mg. daily for chloroquine and 100–200 mg. for sontochin. The results obtained with *P. vivax* and *P. falciparum*, as well as with mixed infections in the field type of experiment, were identical with those obtained with mepacrine. Both drugs

suppressed vivax malaria and suppressed and radically cured falciparum infections. Subinoculations on the eighth day in falciparum infections and on the ninth and tenth day in vivax infection proved positive, showing that infection had occurred and that no inhibitory or lethal action was being exerted on the pre-erythrocytic forms. Subinoculations on the twenty-first day after exposure were negative in falciparum infections, indicating radical cure; none of these volunteers subsequently developed overt malaria. Significant toxic reactions or skin discoloration were not noted with either drug.

Field trials are still in progress, using chloroquine diphosphate in a dosage of 0.5 g. (0.3 g. base) once weekly. Coatney (1949) states that, in Panama, Clarke found that this regimen resulted in almost complete protection against the three common species of human malaria parasite, and Field (1949) has reported very favourable results from Malaya.

2. Causal Prophylaxis by Drug Action on Pre-erythrocytic Forms

Two groups of compounds possess such an action—the 8-amino-quinolines and the biguanides. As it is necessary to use pamaquin or pentaquine in toxic dosage to get a causal prophylactic effect they need not be further considered.

The brilliant researches of Curd, Davey, and Rose (1945) culminated in the synthesis of the biguanides and the discovery of their causal prophylactic and therapeutic action in bird malaria. It was arranged through Dr. C. M. Scott and the Medical Research Council for investigations on their suppressive and causal prophylactic action to be undertaken at Cairns by Fairley and his colleagues (1946a). Over 200 volunteers were used in these experiments on paludrine (proguanil) alone.

Proguanil

When volunteers were exposed to infective biting by falciparum-infected mosquitoes while taking proguanil in a daily dosage of 100 mg. no minor symptoms of malaria appeared, parasites were never demonstrable in the blood by microscopical examination, and subinoculation from the seventh day onwards was invariably negative. This result indicated that the primary wave of erythrocytic merozoites arising from rupture of the pre-erythrocytic schizonts was either delayed or failed to appear. Proguanil administration ceased some 21 days after exposure, and the subsequent failure to develop overt attacks of malaria or demonstrable parasites in the blood indicated that destruction of the pre-erythrocytic parasites had been achieved. In other words the drug was acting as a true causal prophylactic.

Similar results regarding suppression and negative subinoculations were obtained in volunteers experimentally infected with *P. vivax* while taking 100 mg. of proguanil daily, except that after ceasing to take the drug they ultimately developed overt vivax malaria. Proguanil was here acting only as a partial causal prophylactic, inhibiting pre-erythrocytic schizogony but not destroying the tissue phase of the parasite.

Similarly, in field experiments where volunteers were bitten by as many as 250 mosquitoes containing either falciparum or vivax sporozoites in their salivary glands, suppression was complete during the daily administration of proguanil (100 mg.). Some 24 to 33 days after the last dose of proguanil overt vivax malaria developed.

Single-dose Regimen in Prophylaxis

Subsequent experiments showed that proguanil in a single dose of 50–100 mg., given at any time between the 39th and 131st hours after a single exposure to falciparum-infected mosquitoes, acted as a complete causal prophylactic and entirely eradicated infection in the pre-erythrocytic stage. A single dose of 300 mg. given three hours before or three hours after exposure to infection failed to protect; so it did at 168 hours, though at 144 hours it gave protection. These findings indicated that the pre-erythrocytic forms were much more susceptible to the action of proguanil than either the sporozoites or the first generation of erythrocytic merozoites which would be escaping into the circulation about this time—i.e., on the seventh day.

In native labour groups comprising partial-immunes it is convenient to administer a prophylactic drug at weekly intervals. In doing so with proguanil, however, it is important to appreciate that 300 mg. once weekly may not prevent merozoites of even the most proguanil-sensitive strains of *P. falciparum* gaining access to the blood stream if the individual has been infected six to seven days previously. Furthermore the individual would still be vulnerable to reinfection with *P. falciparum* on the eighth day if bitten by infective mosquitoes some hours before or a few hours after the weekly dose of proguanil had been taken. Subsequent suppression and radical cure would then depend on the schizonticidal action of the drug, and if the strain of *P. falciparum* happened to be relatively insensitive to proguanil in this respect occasional break-throughs with overt attacks would not be surprising. In such circumstances, once overt falciparum malaria develops it is essential to establish radical cure before the patient reverts to prophylactic proguanil.

Covell *et al.* (1949b) investigated the causal prophylactic action of proguanil in patients infected with a West African strain of *P. falciparum* which was relatively insensitive to the schizonticidal action of that drug. They found, even with this strain, that complete protection was afforded and malaria prevented by proguanil when given in doses of (1) 50 or 100 mg. daily, (2) 100 mg. twice a week at intervals of three or four days, or (3) 300 mg. once weekly.

With Europeans or non-immunes generally, experience has shown the best regimen to adopt is one tablet (0.1 g.) of proguanil taken regularly every day at the same time so that it becomes a habit. Provided the individual is completely free from malaria when suppressive proguanil is begun, this regimen should lead to the prevention of falciparum malaria and to the suppression of benign tertian and quartan malaria, though not to their radical cure.

Proguanil-resistant Strains

Following the administration of subcurative dosage of proguanil during a series of overt attacks, proguanil-resistant strains have been recorded as developing in *P. gallinaceum* in chicks by Bishop and Birkett (1947) and Williamson, Bertram, and Lourie (1947), and in *P. cynomolgi* in monkeys by Hawking and Perry (1948) and Schmidt *et al.* (1949). Such proguanil-resistance may appear within two and a half months, when the full impact of treatment must fall on the early erythrocytic parasites. Proguanil-resistance, once developed, is retained on successive transmission through both sporozoite-infected birds and monkeys. Rollo, Williamson, and Lourie (1948) failed to produce resistance when the treatment was administered in latent infections—i.e., after the phase of acute parasitaemia—even when treatment twice daily was continued for one

year; in these circumstances treatment fell mainly, if not exclusively, on the exo-erythrocytic forms.

Seaton and Lourie (1949) produced resistance to proguanil in a strain of *P. vivax* by giving small doses of the drug to consecutive patients in whom the strain was being maintained by blood inoculation. The resistance was unaffected by passage through mosquitoes. Resistance was produced under highly artificial conditions over a period of 20 months, but only during the last few weeks had the resistance risen to doses within the range of those ordinarily in use for either suppression or treatment of malaria. They concluded that the danger of producing a serious degree of resistance in a strain of *P. vivax* by the ordinary use of proguanil in clinical practice was slight, if not negligible, both in the treatment of the clinical attacks and in prolonged use of the drug for prophylactic purposes.

In Australia, where many thousands of patients with relapsing vivax malaria were treated with proguanil or other drugs during the acute attack and subsequently received proguanil (0.1 g.) bi-weekly for six months or longer, increased resistance to the drug was not found.

Though proguanil-resistant strains have been produced in man and monkeys experimentally, the conditions underlying their production have been highly artificial. Time alone will reveal if they have practical significance in clinical practice. Fortunately, when a strain of parasite becomes drug-resistant it does so for one particular antimalarial drug or group of drugs and not for others. This appears to be the case whether the resistant strain has been produced experimentally or naturally, as in the Itape-Wewak strain of *P. falciparum* which was relatively insensitive to mepacrine. It follows that when a drug is being used for suppressive or prophylactic purposes the development of specific drug resistance by a given strain of parasite can be circumvented by the substitution of another antimalarial drug of a different group.

Schizonticidal Drugs (Asexual Erythrocytic Parasites)

The clinical cure of overt malaria generally presents little difficulty, while the clinical and radical cure of falciparum malaria in particular is most satisfactory unless there is profound hyperinfection or the strain of parasite is unduly insensitive to the schizonticide employed.

Routine treatment for the overt attack of malaria in the Australian Army consisted of 30 gr. (2 g.) of quinine for three days, mepacrine for the next five days, and pamaquine (base) 10 mg. thrice daily for three to five days. At first mepacrine was given in a dosage of 0.3 g. daily from the fourth to the eighth day; later it was increased to 0.6 g. daily on the fourth and fifth days, and 0.3 g. daily on the sixth, seventh, and eighth days. Then a maintenance dose of mepacrine (0.1 g.) was given daily for six weeks. In all clinically severe cases of overt malaria and in hyperinfections intravenous quinine (10 gr.) was given without delay and repeated where necessary.

This combined therapy was most effective. Radical cure of falciparum malaria generally resulted, carriers were eliminated, and the malaria mortality rate was extraordinarily low, not exceeding 1 per 1,000 in treated cases, including complications.

Quinine.—It has been appreciated for many years that clinical and radical cure of overt malaria by quinine could be achieved with most strains of *P. falciparum* if 10 gr. was administered thrice daily for three weeks. Furthermore, the use of quinine is entirely free from the danger of precipitating true blackwater fever in primary falciparum malaria, as this complication arises only in the presence of chronic latent or recrudescing falciparum infections.

Mepacrine.—The schizonticidal properties of mepacrine were well known before the war, but the work of Shannon *et al.* (1944) in establishing the pharmacological basis for its more rational use was outstanding. Their investigations showed that mepacrine is extensively localized in the tissues and that its effectiveness as a schizonticide is a function of its concentration in the plasma. A large loading dose was recommended during the first day (1 g. in divided doses) to obtain rapid saturation of the tissues and a high plasma level; this resulted in a more rapid clinical response, especially in falciparum malaria.

Reference has already been made to the schizonticidal action possessed by the 4-amino-quinolines when given in suppressive dosage, and this is also manifest in their effectiveness in rapidly controlling clinical attacks.

Chloroquine.—This drug is probably the most potent schizonticide yet discovered. Berliner *et al.* (1947) state that it is superior to mepacrine owing to its lower toxicity, its small dosage, and the small drug concentration required to produce a given effect. Coatney (1949) reports that in falciparum malaria three or four days' treatment with chloroquine gives better results than a week's treatment with mepacrine, and that it is the drug of choice in the treatment of the acute attack. The course advocated consists of 2.5 g. of chloroquine diphosphate administered over three days. Since chloroquine, like mepacrine, is extensively stored in the tissues, a large initial dose (1.5 g.) is advised on the first day of therapy in order to get an adequate plasma concentration. If chloroquine can produce radical cure of the different strains of falciparum malaria with regularity in non-immunes after three days' treatment unassociated with toxic symptoms it is superior to other schizonticides. It produces clinical cure of benign tertian and quartan malaria, but there is no evidence that it is more effective than other schizonticides in producing radical cure.

Proguanil.—Maegraith and his colleagues (1945) treated 22 patients naturally infected with West African strains of *P. falciparum* with proguanil, the dosage varying from 50 to 600 mg. twice daily. The clinical and parasitological response was satisfactory in all instances, but it was not feasible to determine the radical cure rate. Fairley *et al.* (1946a) reported radical cure in 45 out of 46 experimentally induced sporozoite infections and in 41 out of 41 natural infections with New Guinea strains of *P. falciparum*.

Therapeutic trials have been generally satisfactory in Malaya and India, but results in Africa have been widely divergent, some being satisfactory, others the reverse. With the object of clarifying this problem, Covell and his colleagues (1949a) recently investigated the action of proguanil in infections with a West African (Lagos) strain of *P. falciparum* in the treatment of overt attacks. Nine out of 10 patients with overt primary malaria treated with 0.3 g. of proguanil twice daily for 10 days had recrudescences after three weeks. Despite a second similar course, three patients had recrudescences later. When patients infected with this strain received 0.6 g. of proguanil daily for 10 days, reinforced on the first day of treatment by either quinine (2 g.) or mepacrine (0.9 g.), radical cure resulted in all instances. Until more is known about the therapeutic response to infection with falciparum strains in other parts of Africa, and indeed in falciparum infections generally, it would seem advisable to reinforce the schizonticidal action of proguanil with mepacrine. As an alternative to 0.9 g. of mepacrine on the first day only, a dosage of 0.2 g. thrice daily on the first day and 0.1 g. thrice daily on the second and third days should be well tolerated and prove satisfactory for this purpose.

In volunteers infected with New Guinea strains of *P. falciparum* treatment was instituted at variable periods after exposure to infections, from the time sporozoites first entered the blood on the seventh day before fever had started to some weeks after its onset. No significant difference was noted between early- and late-treated cases, so the development of partial immunity could not be the factor responsible for the high radical cure rate obtained.

The most likely explanation of the different therapeutic results is that these two different geographical strains vary

markedly in their sensitivity to the schizonticidal action of proguanil, the New Guinea strain being very sensitive and the Lagos strain relatively insensitive.

Single-dose Regime for Treatment of Overt Malaria

One of the remarkable features of proguanil is that a small single dose of the drug will frequently control the clinical attack. This was first noted at Cairns in several non-immune volunteers who were suffering from overt falciparum malaria with high parasite densities; a single tablet (100 mg.) resulted in clinical cure and temporary disappearance of parasites in thick blood films. Parasites, however, shortly reappeared and clinical recrudescences occurred. A similar effect was also observed in vivax infections.

The advantages of such single-dose therapy among native populations with partial immunity are obvious. Field trials have been made in Malaya, India, and elsewhere—generally with favourable results. The dose usually adopted for this purpose has been 0.3 g. In India, Afridi *et al.* (1947) considered that 0.3 g. was the optimum single dose of proguanil, and found it sufficient for the clinical cure of overt falciparum and vivax malaria in a high proportion of cases. Field (1949) compared the effects of 0.6 g. of mepacrine given on one day in divided doses and one single dose of 0.3 g. of proguanil in the treatment of overt malaria in Malaya. The larger dose of mepacrine was used because it was found that 0.3 g. was not effective in falciparum malaria. The disappearance of parasitaemia was quicker in overt falciparum malaria with proguanil than with mepacrine and slower in benign tertian and quartan overt malaria. The disappearance of fever was slower with proguanil than with mepacrine in all forms of malaria, but the sense of well-being in the proguanil-treated cases was stressed.

In prophylaxis the high suppressive action of proguanil was confirmed in falciparum and vivax malaria, and little difference was noted between a dosage of 0.1, 0.2, or 0.3 g. given once a week.

Drugs Acting on Exo-erythrocytic Forms (8-amino-quinolines)

Clinical cure of vivax malaria with any of the well-known schizonticidal drugs like quinine, mepacrine, or chloroquine is highly satisfactory, but radical cure is not. There is no evidence that any of these drugs destroy the late exo-erythrocytic forms which are responsible for relapses. Proguanil, even in small dosage, is an effective though somewhat slower schizonticide for vivax malaria. It slows up or temporarily inhibits schizogony in the pre-erythrocytic phase if administered over the first week after infection, but there is no evidence that it affects later tissue forms so as to produce radical cure. For such a result we have to turn to the 8-amino-quinolines, of which the best-known compounds are pamaquin, pentaquine, and iso-pentaquine.

Pamaquin.—The first demonstration of the radical cure of vivax malaria by one of these drugs was made by Sinton and Bird (1928) in India. They reported that while 70% of patients with chronic malaria treated with quinine relapsed, only 30% of those treated with pamaquin did so; when quinine was administered simultaneously with pamaquin, as in "plasmoquine co.," the relapse rate was reduced to 8.5%. These results were confirmed in India and elsewhere, but owing to the troublesome toxic effects this effective combined treatment for recurrent vivax infections unfortunately lapsed. It was revived in the later stages of the recent war, and radical cure rates approximating to 80% were generally obtained in natural vivax infections treated with 2 g. of quinine and 30 mg. of pamaquin (base) daily for 12 to 14 days. In Australia proguanil (0.3 g. daily) combined with pamaquin (30 mg. daily) was given for 12 to 14 days, with results which were comparable to those obtained in a similar series treated with quinine and pamaquin, except that relapses appeared somewhat later in the proguanil–pamaquin series. With proguanil (0.3 daily), toxic complications were no more common than with quinine. Monk (1948) concluded that this treatment was likely to prove at least as successful as quinine–pamaquin therapy.

Pentaquine and Iso-pentaquine.—After 1944 much of the American war effort in regard to antimalarials was expended in attempting to find an 8-amino-quinoline derivative which was curative for vivax malaria and less toxic than pamaquin. Alving *et al.* (1947) in a clinical trial of 18 analogues of pentaquine concluded that per kilogram of body weight pentaquine has greater curative activity and lower toxicity than pamaquin. Coatney (1949) reports two of these compounds—pentaquine and iso-pentaquine—to be superior to pamaquin. The dosage generally advocated consists of quinine sulphate 2 g. and pentaquine (base) 60 mg. daily for 10 to 14 days. Its radical curative action in overt vivax malaria has been shown by Loeb (1946), Monk (1948), and others. White *et al.* (1948) have also shown that this treatment is just as effective when given during the latent phase of *P. vivax* in the complete absence of erythrocytic parasites. The action of the drug in these circumstances can only be on late exo-erythrocytic forms.

Identical toxic reactions appear to arise with pamaquin, pentaquine, and other 8-amino-quinolines. They include gastro-intestinal disturbances, methaemoglobinanaemia, and haemolytic anaemia supervening on the third to fifth day of treatment. Rosenfeld, Zubrod, *et al.* (1948) and Blake (1948) found that methaemalbumin consistently appeared in the serum of individuals receiving quinine and pamaquin concurrently. These findings signify that the administration of quinine and pamaquin and probably other 8-amino-quinoline derivatives is always associated with some degree of intravascular haemolysis, which in certain instances produce frank haemolytic anaemia and in rare cases haemoglobinuria.

The toxic manifestations and the radical-cure rate in vivax malaria, associated with pentaquine–quinine and pamaquin–quinine combined treatments, seem so similar that it is difficult to assess their exact status at the present time. Treatment with any of the 8-amino-quinoline group of drugs should be under medical supervision.

Gametocidal Drugs

The treatment of the malaria carrier has often attracted less attention than it merited. In hyperendemic areas of malaria effective carriers are found essentially in infants and young children and not in the older members of the community who have become immune as a result of repeated infection. The individual possessing solid immunity and tolerance may harbour asexual but not sexual parasites in the blood. On the other hand, non-immune adults who develop primary malaria become effective carriers if the primary trophozoite wave is not rapidly cut short by therapy; this is a major factor in the development of epidemics in unsalted troops in malarious areas.

While quinine and mepacrine are reasonably effective primary gametocides in infections with *P. vivax* and *P. malariae*, they do not exert any deleterious action on the mature gametocytes of *P. falciparum*. Pamaquin, on the other hand, is a polyvalent gametocide and even in minute doses (10–20 mg. base) renders falciparum gametocytes non-infectious to mosquitoes within 24 hours, and causes their disappearance from the blood in three to four days.

Mackerras and Ercole (1947) found that when proguanil was given in a dosage of 0.1 to 0.3 g. daily to falciparum or vivax gametocyte carriers (New Guinea strains) no effect was observed on the number or microscopical appearance of the gametocytes in the blood. Only when given very early in the attack was gametocyte production affected by proguanil, and then only indirectly, because the primary trophozoite wave was checked before gametogony had started.

In the stomach of the mosquito ingested falciparum or vivax gametocytes may undergo exflagellation and fertilization and even produce small oöcysts, but development ceases at this point and the oöcysts die if proguanil is present even in small quantities in the blood feed. Complete sterilization of the gut infection in mosquitoes results some one to two hours after 0.15 g. of proguanil has been administered to a carrier. In mosquitoes fed on the second day vermicules may form, but in those fed on the third or fourth day of proguanil administration neither vermicules nor oöcysts are detected. The same effect was produced by letting mosquitoes first engorge partially on a normal person taking 0.1 g. of proguanil daily and then allowing them to complete their feed on a carrier with plentiful gametocytes in the blood.

Shute and Maryon (1948) confirmed these findings with the Rumanian strain of *P. falciparum* and suggested it was the female gametocytes on which the drug acted.

These experimental findings imply that it would be difficult for salivary-gland infections to become established in the local anophelines when they are feeding on the blood of people who are taking proguanil regularly. Thus the daily administration of proguanil to a military force in a hyperendemic area would not only be acting as a causal or partial causal prophylactic in individuals inoculated with sporozoites but by inhibiting the development of the sexual cycle in the mosquito it would be a potent factor in limiting transmission and preventing the development of epidemics.

Comment and Conclusions

In conclusion, I would remark that during the past decade we have learnt how to use and when not to use the older antimalarial drugs like quinine, pamaquin, and mepacrine. During this period several potent antimalarial drugs have been discovered or rediscovered and their therapeutic action worked out with considerable exactitude. Proguanil is unique among these owing to (1) its true causal prophylactic action in falciparum malaria, (2) the schizonticidal effect often exerted by a single small-dose in overt malaria, and (3) its polyvalent gametocidal properties. Chloroquine is probably the most potent schizonticide yet discovered; it is of great value both as a schizonticidal suppressant given once weekly and in the intensive treatment of the overt attack. For the radical cure of benign tertian malaria pentaquine and iso-pentaquine are now becoming available; just how superior they are to pamaquin when given in combination with quinine future work will decide.

Malaria casualties in non-immune troops operating in hyperendemic areas could be prevented or kept at an insignificantly low level by the routine administration under supervision of such drugs as mepacrine, proguanil, and chloroquine in correct dosage. During military operations it would be advisable to have stock-piles of two such antimalarial drugs for suppressive or prophylactic purposes, since the development of resistance to any particular antimalarial drug is specific and can be circumvented by the substitution of another drug of a different group.

THE NATURAL HISTORY OF ASTHMA

A REVIEW OF 300 CASES

BY

ELSIE O. WILLIAMS, M.B., Ch.B., D.P.H.

AND

G. E. O. WILLIAMS, M.D., M.R.C.P.

Assistant Physician, Birmingham United Hospital; late Medical Registrar, Liverpool Royal Infirmary

It is known that asthma is a disease varied in its causation but unvarying in its mechanism, essentially involving contraction of the smooth muscle of the bronchioles. This contraction may occur in response to any of a wide range of stimuli—inflammatory, allergic, mechanical, reflex, psychological, endocrine. Such factors may be "aetiological" (inducing the first of the patient's attacks) or "aggravating" (being concerned in the precipitation of subsequent attacks). The former may act either centrally, by increasing the patient's sensitivity to asthmogenic agents, or peripherally, by producing a permanent state of irritability of the respiratory mucosa or musculature, whereby an attack of asthma occurs in response to appropriate stimulation. Aetiological and aggravating factors may be identical or they may be apparently unrelated. For example, in many instances asthma may be initiated by some endocrine crisis such as puberty or pregnancy, or by acute respiratory infection, but the same patient may nevertheless have subsequent attacks brought on by a

completely different aggravating factor such as dust, exertion, or psychological shock.

In brief, the genesis of asthma may be said to be a triple phenomenon, depending, first, upon the establishment of the "asthma diathesis," in which a family history of allergic diseases, previous allergic manifestations in the patient, and organic abnormalities in the bronchial tree or upper respiratory tract are also known to be significant. The other essential elements are the presence of aetiological factors and exposure to aggravating stimuli.

With a view to correlating the rates of incidence of the above factors and assessing their relative significance the case records of some 300 cases treated at the Liverpool Royal Infirmary Asthma Clinic between 1935 and 1940 have been surveyed.

Signs of the "Asthma Diathesis"

Family History.—Previous allergic disease in the family was found in 51% of 147 males, and in 50.6% of 158 females. In this series at least one member of the patient's family (parents, grandparents, brothers, sisters, uncles, aunts, or cousins) had suffered from asthma, hay-fever, urticaria, eczema, migraine, or epilepsy. Sometimes there were many such instances in the family, and it was found that 22.5% of the males, and 24% of the females had two or more members of the family so affected. Of 141 non-asthmatic patients in the same hospital, a group representing the same class of population, only 12.2% gave "positive" family histories. These findings are very similar to those of Coke (1927) but differ from those quoted by Witts (1934), who found a 60% incidence of "positive" family histories, and more significant than those of Pearson (1934) and Vaughan (1933), who quote much higher rates of incidence of allergy in families of normal subjects.

Age Incidence.—The present series comprised in all 294 patients—141 males and 153 females. They were classified into two main groups—"F.H. positives" with an allergic family history, and "F.H. negatives" with no such family history—and the incidence of asthma beginning at different age groups is shown in Table I.

TABLE I.—*Incidence of Asthma Related to Sex, Ages of Onset, and Family History*

Age Group	Sex		F.H. Positive	
	Male	Female	Male	Female
0–10 years	60	36	63·3%	75·0%
11–20 ,, ...	21	40	57·1%	45·0%
21–30 ,, ...	18	35	28·0%	34·3%
31–40 ,, ...	13	24	53·8%	54·2%
41–50 ,, ...	14	9	35·7%	44·4%
Over 50 ,, ...	15	9	26·7%	33·3%
Total	141	153	50·0%	50·0%

Possible Effect of Menstruation and Pregnancy in Production of Asthma.—Figs. 1 and 2 illustrate the relative ages at *onset* of asthma in the two sexes, and in Fig. 1 the incidence of "positive" family histories in each age group is also shown. There appears to be quite a close parallel between the incidence of positive family histories in the two sexes and at similar ages of onset (see Table I), but the female incidence curves C and D (Fig. 1) and A (Fig. 2) cross the male incidence curves A and B (Fig. 1) and B (Fig. 2) respectively at age groups 11–20 and remain higher until the ages at onset exceed 40 years, after which the figures in each case become similar. This suggests the possibility of some factor or factors having a different effect in the two sexes, beginning approximately at the time of puberty and having in females an aggravating effect upon the asthma. Female endocrine functions seemed significant in this respect, and reference was therefore made to details of female cases in which the onset of asthma occurred between the ages of 14 and 50 years and in which there was a clear history of aggravation by menstruation, pregnancy, or a combination of both. Of 62 cases in which the ages of onset of asthma were stated, the numbers falling into each decade are shown in Table II.

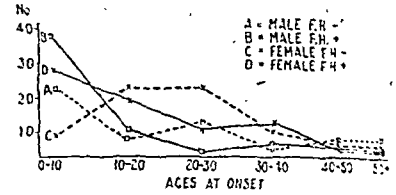

FIG. 1.—Relative incidence of asthma at different ages and subdivided according to sex and family history.

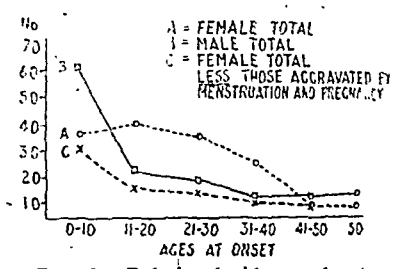

FIG. 2.—Relative incidence of asthma at different age groups, subdivided according to sex and incidence of menstrual or pregnancy aggravation.

TABLE II.—*Incidence of Asthma Aggravated by Menstruation and/or Pregnancy, With Ages of Onset of Symptoms*

Age of Onset:	0–10	11–20	21–30	31–40	41–50
No. of patients ..	5	24	21	11	1

If all such patients are excluded from the total number of females in each age group the remainder represents those in which there is no apparent association with pregnancy or menstruation. They are shown in curve C (Fig. 2), a striking feature of which is its close similarity to that found in males (curve B). Statistical analysis of the figures illustrated by the curves A, B, and C in Fig. 2 shows that the difference between A and B is greater than is likely to be caused by chance ($\chi^2=22.1$, $\eta=5$, $P<0.01$) and that curves C and B differ by amounts which cannot exclude chance as a possible cause ($\chi^2=5.9$, $\eta=5$, $P=0.3$). These findings suggest, therefore, that a proportion of cases of asthma in females may be due to causes associated in some way with female reproductive activity. While it is freely admitted that other associated factors such as psychological changes or reflex sensitivity otherwise enhanced may in many patients have a more direct bearing on the association of asthma with menstruation, evidence is not lacking (Zondek and Bromberg, 1947) that allergic hypersensitivity to the patient's own hormones is by no means rare and may be demonstrated by appropriate skin tests.

Cutaneous Hypersensitivity.—Cutaneous hypersensitivity tests were performed, using Bencard's intradermal and scratch tests for the usual series of allergens. Results were available in 211 cases, and were positive in 35.5%. No comparable series of normal controls was tested, but other workers, such as Pearson (1943), report 20% of positive findings in normal persons, whilst in asthmatic patients the incidence of positives was 75%. On the other hand, Witts's (1934) figures show 40% of positives only among those affected.

It was found that 26 out of 100 "F.H.–" cases were positive to skin tests, while 44% of 111 "F.H.+" cases were positive also on skin-testing. The standard error of these two proportions being 6.42, this difference in the incidence of positive skin tests appears to be statistically significant.

Previous Allergic Manifestations.—Of 246 cases in which the information was available, 40.24% gave a history of one or more of the usually suspected "allergic" manifestations, consisting of the following:

Hay-fever (or vasomotor rhinorrhoea)	39
"Eczema" (including infantile eczema)	54
Migraine	5
Urticaria	12
Epilepsy	2

In 13 cases two of the above conditions occurred together, thus: epilepsy and hay-fever, 1; eczema and hay-fever, 4; migraine and hay-fever, 3; urticaria and eczema, 1; urticaria and migraine, 1; eczema and migraine, 1; urticaria and hay-fever, 2.

It is observed that migraine, though occurring in five patients, does not appear alone, being combined with hay-fever, urticaria, or eczema. Epilepsy occurs once by itself, and once in combination with hay-fever. These findings correspond to those of Witts, in whose series 40–50% of patients had other allergic manifestations, and of Coke, who reports that 22% of his patients had suffered previously from eczema.

Aetiological Factors

Information about factors associated with the onset of asthma was available in 276 cases. The results are shown in Table III. Some light may be thrown on the possible

TABLE III.—*Incidence of Alleged Causal Factors*

Aetiological Factor	Males	Females	Total
No known associated circumstances	50	50	100
Acute respiratory infection (bronchitis, pneumonia, measles, pertussis, etc.)	57	57	114
Psychological "shock" or "worry"	6	8	14
Pregnancy		10	10
Menstruation		5	5
Irritating fumes or dust	7	6	13
Excessive exertion	7	2	9
Miscellaneous causes (food, change of locality, or change of climate)			11

association of allergic tendencies and the nature of the aetiological factors by the data in Table IV, which compares the incidence of positive family histories (F.H.+), skin-test positives (S.T.+), and histories of previous allergic manifestations (P.A.M.) in the four largest aetiological

TABLE IV.—*Incidence of the "Allergic" Features in the Four Principal Aetiological Groups. The Actual Number of Patients in each Group is Shown in Parentheses*

	Aetiological Factors			
	Not Known	Respiratory Infection	Psychological	Pregnancy and Menstruation
F.H.+	50% (97)	55·5% (108)	57% (14)	28·4% (14)
S.T.+	36% (80)	27·4% (73)	36% (9)	12·5% (8)
P.A.M.	36·4% (89)	35·5% (93)	36% (9)	45% (11)

groups. These figures show that, although there is very little difference between the respective incidence of these allergic factors in the first three aetiological groups, in the fourth (pregnancy and menstruation) group the incidence of F.H.+ and S.T.+ is strikingly less, but that of other allergic manifestations somewhat increased. While the figures are too small to warrant definite conclusions, this would add further support to a hypothesis that "menstruation asthma" is truly allergic in origin in a high proportion of cases. The low positive-skin-test incidence would then be explained by the absence of hormonal extracts from the test series, and the low family incidence by the "sex-linked" nature of the allergy, which would be expected to reduce the family incidence of the manifestations to females only.

Aggravating Factors

An attempt was made to compare factors associated with the onset of individual attacks of asthma with those believed to have been concerned in the aetiology of the condition. The results are shown in Table V. These figures

TABLE V.—*Incidence of Aggravating Factors, Grouped According to Aetiological Factors in Numbers of Patients in Each Subgroup*

Aggravating Factors	Aetiological Factors				
	Unknown	Respiratory Infection	Pregnancy and Menstruation	"Dust"	Psychological Trauma
Respiratory infections	14·3% (85)	14·4% (91)	0 (12)	0 (13)	25·0% (12
Food	34·1% (85)	32·2% (91)	16·7% (12)	15·4% (13)	33·3% (12
Psychological disturbances	25·0% (85)	25·5% (91)	18·3% (12)	0 (13)	66·7% (12
Pregnancy and menstruation	28·7% (40)	59·4% (45)	83·3% (12)	66·7% (6)	29·4% (12
"Dust"	22·4% (85)	21·1% (91)	25·0% (12)	92·4% (13)	16·7% (12
Climate	70·6% (85)	55·5% (91)	33·3% (12)	53·9% (13)	50·0% (12
Exertion	35·3% (85)	37·0% (91)	41·5% (12)	15·4% (13)	16·7% (12

show that three out of the four known aetiological factors also aggravate the asthmatic condition in a high percentage of patients. These are, pregnancy and menstruation (aggravated in 83.3%), "dust" (92.4%), and psychological disturbances (66.7%). Respiratory infections, on the other hand, differ markedly in that in only 14.4% of patients was the asthma aggravated by further respiratory infections. Thus it would appear that, while acute respiratory infections have initiated asthma so often that their association is unlikely to be fortuitous, subsequent attacks of asthma are surprisingly seldom occasioned by recurrences of respiratory infection. This might perhaps be explained on the assumption that the respiratory centre, or some other portion of the mechanism governing the tone of bronchiolar muscle, may have received a non-specific sensitization from the original infection which has facilitated an "asthmogenic" response to other stimuli, and may, in fact, establish the "asthma diathesis."

The relationships of aetiological to exacerbating factors may be summarized provisionally by their classification as follows:

Class A.—Factors which initiate the asthmatic condition and exacerbate asthma in a high proportion of cases. These are pregnancy and menstruation, "house dust," pollens, and psychological disturbances.

Class B.—Factors which are apparently associated with the aetiology of the asthma, but not with its subsequent aggravation, such as acute respiratory infection.

Class C.—Factors which frequently aggravate asthmatic attacks, but seldom seem to have played a part in the aetiology of the condition. These are food sensitivity, climatic conditions, and exertion. Together with dust and emotional upsets, such stimuli are well-known aggravators of any respiratory disturbances, particularly cough and dyspnoea.

Clinical and Other Findings in Cases of Asthma

No obvious abnormality was found on clinical examination in 122 out of 251 patients. As might be expected, where physical signs were present the vast majority of patients showed rhonchi. Obvious emphysema was found in 15 patients in this series. Only five of the patients had gross chest deformity (pigeon-breast, kyphosis, or "sunken chest"), the onset of asthma occurring in early life in four of them.

Radiologically, out of 196 patients whose films were available, 66 showed some abnormality—50 had chronic inflammatory changes only, four had old healed tuberculosis.

one active tuberculosis, four pulmonary fibrosis, three emphysema, two pleural thickening, and two cardiac dilatation.

Of 260 patients in whom the upper respiratory tract had been examined, no abnormality of nose, throat, or sinuses was found in 120. Of the rest, 66 had inflammatory lesions of the sinuses, throat, or nose, and 74 showed evidence of changes attributable to allergy only, such as vasomotor rhinitis, simple mucosal oedema, or polyp formation.

Progress

A questionary was circulated to 150 patients who had attended the asthma clinic between 1935 and 1940. Of these, 64 replied; their general progress is shown in Table VI.

TABLE VI.—*Results as Compiled from a Questionary*

Result	Males	Females	Total
"Cured" (i.e., no attacks for at least one year)	7	5	12
Died	7	4	11
Improved	13	9	22
Unchanged	4	2	6
Worse	4	9	13

Recoveries.—In the 12 instances of recovery the condition resolved suddenly in six, and gradually in the remainder. The mean duration of asthma in these cases was nine years. The alleged causes of cessation of the attacks are shown in Table VII. In two patients recovery was attributed to more than one cause.

TABLE VII.—*Alleged Causes of Recovery*

Causes	No.	Ages at Onset	Duration
"Grew out of the asthma"	3	15, 2, 3 years	2, 10, 11 years
Change of environment (war evacuation)	3	2, 2, 1 year	8, 14, 12 ,,
Cautery of nose	2	21, 48 years	23, 10 years
Specific protein desensitization	1	25 years	8 years
Tonsillectomy	1	2 ,,	8 ,,
Breathing exercises	1	2 ,,	14 ,,
Senility	1	57 ,,	24 ,,
Unknown	2	44, 29 years	10, 8 years

Eight of the above 12 patients therefore seem to have recovered without any active therapy, six of these being children. Analysis did not reveal any correlation between age of onset of asthma and ultimate prognosis.

Remedies Found Effective in Attacks.—From the nature of the information received from patients no accurate account could be compiled of the details of treatment found most helpful. It is of interest, however, to find that among the patients who did give a reasonably clear answer the use of one or more proprietary inhalants was considered to have been more effective than medicine from a bottle or than ephedrine tablets.

Discussion

From the above results several points emerge. First, there is support for the accepted view that most cases of asthma are of allergic origin, differences being dependent more upon variations in the nature of the allergic stimuli and their mode of action than upon departure from the allergic process. Secondly, the evidence implicating hormonal activity in the production of asthma is strongly suggestive and lends support to more conclusive findings by other workers regarding the allergic nature of this association (Zondek and Bromberg, 1947).

Clinical abnormalities in the chest (apart from wheezing) were remarkably few, and more interesting still was the rarity of any gross deformity of the chest, particularly when it is considered that in approximately 30% of this group of patients the asthma began in the first decade of life.

Unfortunately our records are not informative enough to enable conclusions to be drawn on the efficacy or otherwise of treatment of nasal sinuses or tonsillar abnormalities in relation to asthma. These conditions appear to fall into two main categories. The first, occurring in 25% of patients, consist of oedema of the nasal mucosa, polyp formation, and other non-inflammatory conditions, which are all possibly of allergic origin, and therefore probably symptomatic of the allergic state of which asthma is but another manifestation (Rackemann, 1937). The second group, including true sinusitis, infected tonsils, and chronic (infective) nasal catarrh, occurred in about 28% of all cases of asthma, and may be aetiologically significant. Although the results of active treatment of upper respiratory diseases has generally been found disappointing (Witts, 1934), it is possible that better results might follow treatment if it were confined to those in the latter group.

Mortality and Morbidity.—This series of cases is spread over a period of between seven and twelve years. It would therefore not be of value to compare the mortality here with that of groups observed over a much shorter period (e.g., Coke, 1927). An adequate follow-up of hospital patients is not always possible, for many drift elsewhere, and others for various reasons do not reply to letters. Of the 64 patients of whom later information was obtained 11 had died within the period—a somewhat surprising mortality of 17.2%; three had developed phthisis in the course of their asthma and died of the disease; three died as a direct result of their asthmatic attacks, and three others died of secondary cardiac failure. That asthma is potentially a fatal disease is too often overlooked, and the above figures underline the importance of long-term treatment in an attempt to safeguard the patient's future. While it is true that the patient must "learn to live with his asthma," it is clear that life would be both happier and longer in its absence.

Summary and Conclusions

Clinical and other findings in 294 cases of asthma have been examined with the object of analysing the natural history of the disease, its aetiology, and its prognosis. Evidence was obtained of the importance of the allergic factor, particularly of the relevance of hormonal allergy in the production of asthma in women. Comparison of the incidence of aetiological factors relative to those aggravating the condition suggests that the factors involved in the production of the asthmatic state may be of three kinds: aetiological and aggravating, aetiological but not aggravating, and aggravating but not apparently connected with aetiology.

From a relatively small series of cases which were followed up over a period of seven to twelve years, 19.4% had apparently fully recovered, while 17.2% had died. This mortality rate, though occurring in a series too small to warrant statistical analysis, nevertheless suggests that asthma as a potentially fatal disease has received rather less attention than it deserves.

We are particularly indebted to our former teacher and chief, Dr. Robert Coope, both for his permission to use the records of the Liverpool Royal Infirmary Asthma Clinic and for his kindly advice and helpful criticism during the production of this paper.

ANTIHISTAMINES IN BRONCHIAL ASTHMA

BY

HERBERT HERXHEIMER, L.R.C.P.&S.Ed. L.R.F.P.S.Glas.

(From the Surgical Unit and Chest Department, University College Hospital, London)

The beneficial action of antihistamines in hay-fever, perennial rhinitis, and urticaria is undisputed, but their use in human asthma has been doubted. In this paper experimental and clinical evidence is presented that the antihistamines are of considerable value in the treatment of this condition.

Experimental Evidence

Method

Bronchial spasm was induced in normal and asthmatic subjects by the aerosol inhalation of spasmogenic substances. This method avoided the risk connected with their parenteral injection in asthmatic subjects, whose response varies so widely; furthermore, their local application imitates the natural conditions more closely and avoids the danger of producing a strong general reaction.

The aerosol was produced by a pressure pump (kindly supplied by Messrs. Aerosols, Ltd.) to which a series of commercial nebulizers were attached. The unit was incorporated in the inspiratory part of the breathing circuit of a recording spirometer (Herxheimer, 1949a). The efficiency of the aerosol so produced can be judged from the fact that when isopropylnoradrenaline was inhaled a 0.25% solution produced similar effects in the same time as a 1% solution administered by a hand-operated inhaler.

As the amount of any drug inhaled cannot be determined accurately, the time of administration was counted in seconds. The degree of bronchial spasm was estimated by measuring the vital capacity, to which it was directly related (Curry, 1946). The maximum breathing capacity cannot be used as a test, as the overbreathing has in many cases a direct influence on the degree of spasm. Other tests which are based on the time required for full expiration do not seem to present any advantage. It is believed that the determination of the vital capacity is fully reliable provided that the thoracic cage is mobile and that there is no venous congestion.

The vital capacity was determined three times before each experiment and the mean was taken as the base-line. Subjects who could not produce three vital capacities within a range of 150 c.cm. were excluded. The spasmogenic substances used were 3% histamine acid phosphate, 2.5% acetyl-β-methylcholine chloride, and allergenic extracts of mixed pollen and of mixed inhalants, made extra strong for this purpose by Bencard's. For the relief of spasm isopropylnoradrenaline was used in 0.25% to 1% solution, pyribenzamine in 1.5% and other concentrations, and sometimes ephedrine and "chlorothen." In all cases one drop of glycerin was added to 2 ml. of the solution, except in the case of acetyl-β-methylcholine chloride, which was dissolved in propylene glycol. If bronchial spasm so produced did not subside spontaneously an antispasmodic was given after some time and immediate relief obtained. In other experiments with the same subjects an antihistamine substance was given beforehand orally or, in a few cases, as an aerosol, and the spasmogenic aerosol inhaled for the same time as before.

In a number of control experiments with the same subjects various substances were inhaled as aerosols—physiological saline, allergenic extracts, ephedrine in various concentrations, 10% ammonium chloride, aminophylline, and some antihistamines. Saline and ephedrine in low concentrations and ammonium chloride produced no effect, but high concentrations of ephedrine, pyribenzamine, and amethocaine caused reduction of vital capacity and wheezing in asthmatic subjects. In a number of patients genuine asthma was treated in the same way as induced asthma, and in some an antihistamine was given intravenously.

Results

Normal Subjects.—The inhalation of histamine in most cases caused subjective symptoms during the third minute, consisting of redness of the face, sometimes a headache, and a sense of constriction of the chest. Of the 16 subjects three showed no decrease of vital capacity. In two of these higher concentrations of histamine were tried. One showed a decrease after 10% histamine phosphate had been breathed for four minutes; the other showed no decrease. Of the remaining 13 subjects five showed reductions of between 5 and 9% and eight between 12 and 26%. The inhalation of acetyl-β-methylcholine chloride caused fewer and milder general symptoms. In only two cases out of 14 was the vital capacity decreased. This difference may be entirely due to the arbitrarily chosen amounts of aerosol administered. For instance, in one subject the vital capacity decreased after three minutes of inhalation from 4,000 to 3,600 c.cm. with mild general symptoms After four

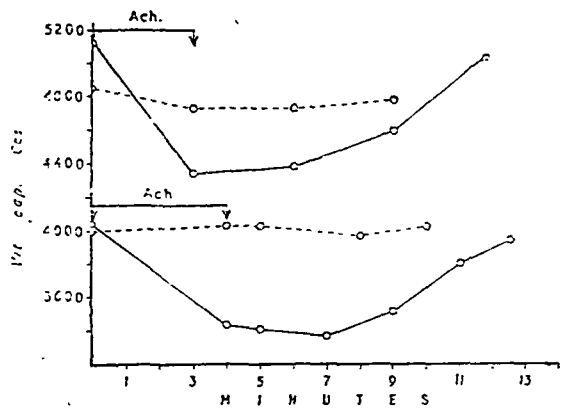

FIG. 1.—Change of vital capacity (as a measure of bronchial obstruction) in two normal subjects who inhaled acetyl-β-methylcholine chloride (Ach.) for three and four minutes. The interrupted lines show the same experiment after 25 and 50 mg. of phenergan had been given beforehand.

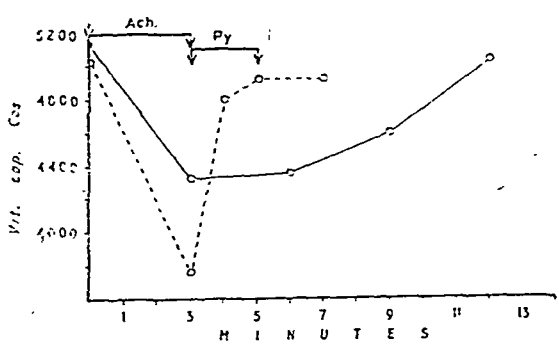

FIG. 2.—Change of vital capacity, representing the degree of bronchial obstruction in a normal subject after inhaling acetyl-β-methylcholine chloride for three minutes (uninterrupted line) and the same when inhaling pyribenzamine (Py.) 1.5% immediately afterwards for two minutes (broken line).

minutes' inhalation the symptoms were more severe, and the vital capacity decreased to 3,360 c.cm. When "phenergan" ("R.P. 3277") was given 90–120 minutes before the experiment the general symptoms were suppressed or reduced to a minimum. The vital capacity did not change. This was the case after histamine as well as after acetyl-β-methylcholine chloride (Fig. 1). In one case the inhalation of 1.5% pyribenzamine, given immediately after the acetyl-β-methylcholine chloride had depressed the vital capacity, very quickly restored it to its normal value (Fig. 2).

Cases of Induced Asthma.—The induction of bronchial spasm—the asthmatic attack—in patients involves some risk, as a very small amount of inhalant may cause a severe attack. In a patient whose reaction to a substance is unknown it is advisable to start with one whiff of the inhalant only and to await the reaction. With histamine and acetyl-β-methylcholine chloride this reaction usually appears at once in full strength. The patient feels tightness of the chest, and when he attempts to breathe out deeply he encounters difficulty not felt before. With allergenic extracts, especially when a very small amount produces a reaction, this difficulty in breathing—the "wheeze" which also indicates a decrease of vital capacity—often does not appear at once. Only a mild tickle or soreness is felt in the throat or in some related region (for instance, the shoulder), and the wheeze develops gradually two to five minutes later.

The protection against attacks induced in this way required more antihistamine than in normal subjects—phenergan was mostly used—and if the induced attack was severe—if, for instance, the vital capacity was reduced by about one-half—no protective effect could be obtained even with 75 mg. of phenergan. If, however, the amount of inhalant was just small enough to induce a mild attack, phenergan or "anthisan" ("neoantergan") suppressed it either completely or at least partly (Figs. 3 and 4). Pyribenzamine as aerosol was effective in partially relieving the induced spasm in some cases, but not in others.

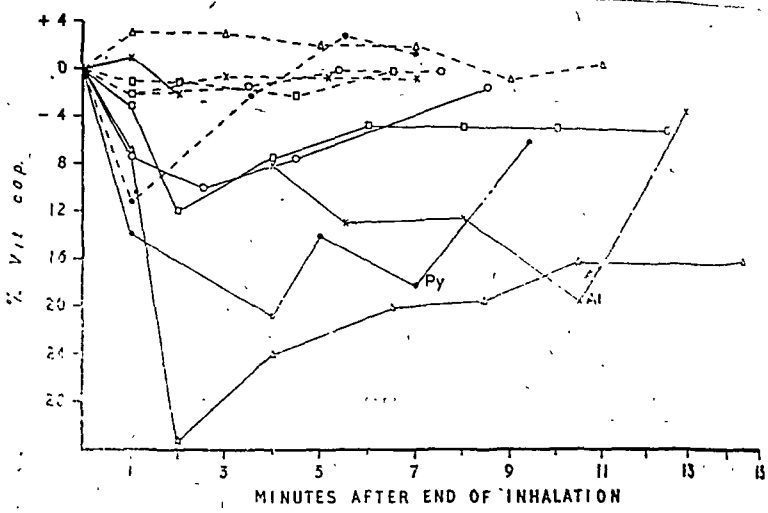

FIG. 4.—Protective action by antihistamines against bronchial asthma induced by mixed pollen inhalation. Five subjects. *Full lines* = Change in vital capacity after inhalation without protection. *Interrupted lines* = Change in vital capacity after varying doses of phenergan had been given beforehand.

Period of inhalation	Dosage of phenergan

× 5 ,, ...	25.0 mg.
○ 30 ,, ...	37.5 mg.
□ 25 ,, ...	37.5 mg.
● 180 ,, ...	50.0 mg.

Py. Al. = Pyribenzamine 1.5% or aleudrine 1% inhaled in order to terminate the asthmatic attack.

Cases of Genuine Asthma.—Pyribenzamine aerosol frequently relieved bronchial spasm. As shown in Table I, in 12 patients the vital capacity was increased by over 200 c.cm. after inhalation of this drug. There were 12 other patients in the group, five of them elderly and sufferers from emphysema, in whom the increase was absent or negligible. Intravenous anthisan often produced marked relief, but the substance must be injected very slowly to avoid vomiting and circulatory collapse (Table II). Three cases in which no increase of vital capacity was obtained are not included in the table. Phenergan injected intravenously had also a beneficial effect (Fig. 5).

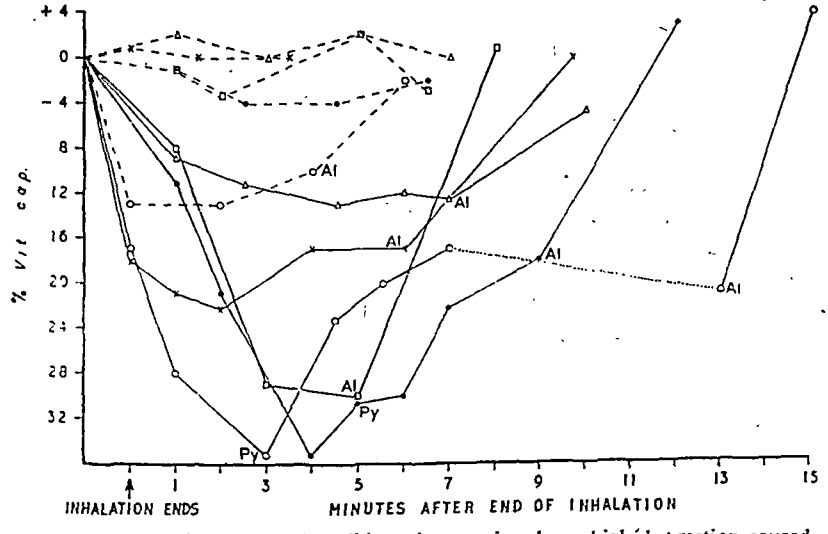

FIG. 3.—Protective action of antihistamines against bronchial obstruction caused by acetyl-methylcholine chloride inhalation. Five subjects. *Full lines* = Change in vital capacity after inhalation without protection. *Interrupted lines* = Change in vital capacity after varying doses of antihistamine had been given beforehand.

Period of inhalation	Dosage of antihistamine
△ 90 sec.	62.5 mg. phenergan

□ 12 ,, ...	50 mg. ,,
● 35 ,, ...	75 mg. ,,

Py. Al. = Pyribenzamine 1.5% or aleudrine 1% inhaled in order to terminate the asthmatic attack.

Clinical Evidence

The spontaneous and rapid changes in the asthmatic condition and the psychological factors which are almost always involved in the aetiology necessitated certain precautions in the selection of patients. Those who showed rapid fluctuations and those with long free intervals were excluded. This left the patients with moderate or mild attacks which occurred frequently and those who were in an asthmatic state.* Of these, only patients were selected who had a long experience of the disease and had tried many remedies, often without success, and thus appeared not unduly prone to suggestion. They had been known to the observer for some time; their reaction to various drugs had been investigated and their seasonal

*The term "asthmatic state" is used in this paper for bronchial spasm continuously present for long periods whether mild, moderate or severe.

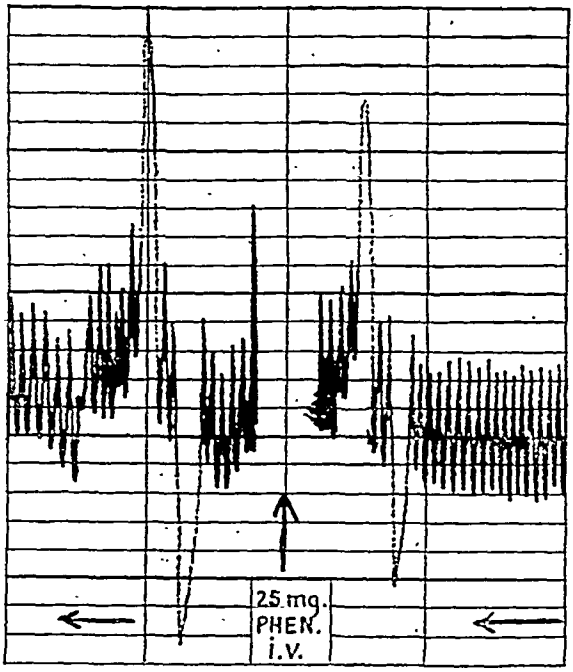

FIG. 5.—Asthmatic state. Vital capacity before (1,700 c.cm.) and 15 minutes after (2,240 c.cm.) intravenous injection of 25 mg. of phenergan.

TABLE I.—*Effect of Pyribenzamine Aerosol in Genuine Asthma*

Case No.	Highest Vital Capacity Ever Recorded	Vital Capacity Before Inhalation	Vital Capacity After Inhalation	Strength of Aerosol (%)
1	3,015	1,620	2,260	5
2	2,960	1,860	2,240	5
3	2,995	1,550	2,190	5
		2,000	2,300	5
		1,680	1,940	1
		2,100	2,650	1
4	2,980	2,290	2,520	5
5	3,900	3,420	3,900	5
6	2,560	2,325	2,550	1
7	2,540	2,330	2,540	1
8	3,690	2,550	3,060	1
9	3,500	2,700	2,960	1

variations were known. Their remedies were changed periodically, sometimes to placebos. These precautions made large-scale controlled experiments with dummy tablets unnecessary, in my opinion. The severity of the individual complaint was conveniently indicated by the number of aerosol inhalations required each day. The aerosol usually contained papaverine, atropine, and either adrenaline or isopropylnoradrenaline. The patients were asked to use their hand inhaler only when the wheeze became intolerable. As a rule they had to inhale on waking and at bedtime, but often four or six inhalations were taken during one night. The reduction in the number of inhalations required was regarded as an indication of the efficacy of an antihistamine substance.

The antihistamines used were mainly anthisan (100–600 mg.), phenergan (25–100 mg.), and "benadryl" (50–250 mg.). These doses were always given at bedtime, as their soporific effect is too great to allow their use during the day. These patients were therefore in need of an antispasmodic in the daytime, and ephedrine was usually given in its optimum amount on waking and after lunch. This combination proved very useful, because ephedrine interferes with sleep and could not be given at bedtime, and two daily doses of it do not cause tolerance. For those intercurrent superimposed attacks not suppressed by antihistamine and ephedrine, isopropylnoradrenaline ("aleudrine") was used either by inhalation or perlingually.

Twenty-six patients improved after receiving anthisan and ephedrine. Thirty-one were given anthisan and phenergan on alternate nights and ephedrine in the daytime, 11 received phenergan and ephedrine, two had phenergan alone, four had anthisan alone, five had benadryl and ephedrine, and two were prescribed benadryl only. All these patients showed definite improvement in the number of inhalations and in their physical efficiency. Three patients with severe chronic asthma and six with mild or moderate chronic asthma obtained no beneficial effects from any of the antihistamines. In others the effect of these drugs could not be assessed because of sudden changes in the character of the disease.

It should be noted that not all of the patients on anthisan reacted well to phenergan, or vice versa, although many of them did. Some of those who did not respond to either were found to respond to benadryl. In no case did we succeed in influencing an acute attack by an oral dose of antihistamine. Night attacks were suppressed only if they were mild attacks superimposed on a moderate asthmatic state, but not if they occurred as comparatively violent spasms after a free interval, frequently seen in the juvenile type of asthma.

Small doses which are satisfactory in hay-fever, urticaria, and perennial rhinitis were not sufficient in the treatment of asthma. The effective evening dose of anthisan was found to be 300–500 mg. and that of phenergan 50–75 mg. Benadryl, in the few cases in which it was effective, was active in small amounts—50–100 mg. Pyribenzamine was not tried; chlorothen and "histadyl" had no definite effects.

The side-effects of the antihistamine drugs varied with the dosage. Both anthisan and phenergan caused drowsiness, which was of longer duration with the latter agent. The action of phenergan was often evident after 12 hours or longer, and its antiasthmatic effect in the early morning after an evening dose was highly desirable. On rare occasions, however, these drugs caused sleeplessness. This effect was particularly noticeable with phenergan, and appears to be more pronounced if an overdose is given. A most undesirable side-effect is the nausea that is often caused by anthisan. This drug should always be taken with food.

No clinical signs were found to discriminate between patients who would or would not be responsive to antihistamines. On the whole I think—and this is not more than an impression—that patients with asthma of extrinsic origin responded more easily, and those in whom the bronchial spasm had developed subsequent to emphysema, less. Young subjects tend to respond more favourably than older persons.

Case Reports

The following are extracts of some representative case histories:

Case 21.—Woman aged 30, October 15, 1948. Asthma since 5 years old. Has been waking up three to four times a night during the last nine months, and has had to inhale a papaverine-atropine mixture which gave relief. Increasingly breathless on exertion; thorax emphysematous; unable to do her work; rhonchi ++. Treatment: anthisan 0.3 g. and phenobarbitone ½ gr. (32 mg.) at bedtime; ephedrine ¾ gr. (50 mg.), later 1¼ gr. (81 mg.), morning and after lunch; "theamin" mid-morning. October 22: Very fair, hardly needed inhaler; breathing exercises started. February 11, 1949: She is occasionally a little breathless on exertion and has then to make use of her inhaler, but she has been very well and fit for her work.

Case 22.—Man aged 36, July 16, 1948. Had nocturnal attacks for three years, which became more frequent when he moved from Southampton to London. He was wheezy during both night and day, and could not sleep much because of breathlessness. Ephedrine previously gave relief, but is now ineffective. On examination: chest barrel-shaped, rhonchi +++, vital capacity 2,980 c.cm. (reduced by about 33%). Treatment: anthisan 0.4 g. at bedtime with phenobarbitone ½ gr. (32 mg.); ephedrine 1½ gr. (97 mg.), later 2 gr. (130 mg.), morning and after lunch. July 23: Much better. No attacks during the night, although he wakes up for short periods. Can move about more easily; sputum much decreased. November 12: Has been very well; only one attack in four months. A little wheezy during fog. March 11, 1949: Unchanged. Vital capacity 4,520 c.cm.

Case 23.—Man aged 22, May 28, 1948. Asthma since the age of 3. Frequent coughs and colds every winter. May be free from wheezing for two to three weeks only. During summer, hay-fever and asthma. "Felsol," ephedrine, and the inhalation of a papaverine-atropine mixture give temporary relief: inhales three times during the day, three times during the night. On examination: chest deformed, kyphosis, rhonchi ++. Treatment: anthisan 0.5 g., plus 1 gr. phenobarbitone (65 mg.) at bedtime, ephedrine 1½ gr. (97 mg.) morning and after lunch; neb. aleudrine 2% for inhalation. August 27: Does not require treatment during the night, but is still wheezy on waking, and then has to make use of his inhaler, but he does not need it during the day. December 10: Has remained well except for one setback caused by an infectious cold, but has now become intolerant to anthisan (diarrhoea and vomiting). Benadryl 200 mg. substituted, but the nocturnal attacks recurred; phenergan 75 mg. permitted the patient to sleep through till 5.30 or 6 a.m., when he had to use the inhaler. No inhalations required during the day. Since then he has been able to complete his training as a bookbinder.

Case 10.—Woman aged 25, May 21, 1948. Asthma since the age of 2½; hay-fever since 10. Asthma worse during the last 10 years. Attacks last from two to four weeks. There may be free intervals of six months or more, but the intervals are not completely free from wheezing. Summer usually worse than winter. Sensitive to small doses of ephedrine. On examination: no signs of emphysema; few expiratory rhonchi; vital capacity normal (3,400 c.cm.). Treatment: anthisan 0.15 g.; later phenergan 25 mg. at bedtime, ephedrine ¼ gr. (16 mg.) morning and midday. Later the ephedrine was replaced by methylephedrine 2/3 gr. (45 mg.). February 25, 1949: Very well. Occasional mild attacks easily checked by aleudrine perlingually.

Case 26.—Man aged 34, August 6, 1948. Asthma since the age of 8. Until six months ago attacks occurred every night and occasionally during the day. They then increased in frequency, but were relieved by the inhalation of a papaverine-atropine mixture. Five weeks ago a severe attack made injections of adrenaline necessary. Has not been free from wheezing since; inhales twice during the night, three times during the day, and needs 5–10 minims (0.3–0.6 ml.) of adrenaline daily. On examination: barrel chest, kyphosis; vital capacity 3,150 c.cm.; rhonchi +++. Treatment: anthisan 0.5 g. at bedtime, which reduced the nocturnal attacks to one. Later, ephedrine 2½ gr. (162 mg.) was given on alternate days, and 75 mg. of phenergan every other night instead of anthisan. Under this regime the patient could sleep through till 5 or 6 a.m., when he had to use his inhaler. Phenergan usually enabled him to sleep about an hour longer than did anthisan. In daytime he had to inhale three to four times, but he did not need adrenaline, and he can now move about without restriction and look after his business.

Case 24.—Woman aged 53, October 1, 1948. Asthmatic attacks for 15 years. For the last three months had frequent attacks, provoked by mild exertion and during the night. Ephedrine ½ gr. (32 mg.) and inhalations of a papaverine-atropine mixture give temporary relief. Believes that her present work with wool caused the deterioration. On examination: chest barrel-shaped, rhonchi +++, vital capacity 1,700 c.cm. Treatment: anthisan 0.3 g., with phenobarbitone ½ gr. (32 mg.) at bedtime and ephedrine 1 gr. (65 mg.) twice in the day, did not have any effect; benadryl 150 mg. plus phenobarbitone 1 gr. (65 mg.) at bedtime improved the condition at night so much that after a week only one inhalation was needed instead of five. Her condition during the day was equally improved by ephedrine 2 gr. (130 mg.) in the morning and after lunch. Breathing exercises were now started. January 28, 1949: Very well; seldom required inhalation. March 11: Well, apart from a transient cold and cough. Sleeps well, is able to move about freely and to do her work. Vital capacity now 2,670 c.cm.

Further case histories are published elsewhere (Herxheimer, 1949b).

Discussion

The evidence that antihistamines have any action against bronchial spasm has so far been received with scepticism It had been shown experimentally that they counteracted bronchial spasm induced by histamine in animals and man (Curry, 1946). Schiller and Lowell (1947) and Curry and Lowell (1948) could not find a protective effect when the bronchial spasm was induced by mecholyl or by the inhalation of allergenic extracts. Unfortunately, they used the weaker antihistamines (benadryl and pyribenzamine) in small amounts, and tried them on a few patients only. From these negative results it appeared as if the histamine-induced bronchospasm were a spasm *sui generis* and had nothing in common with other types of bronchial spasm—for example, that induced by acetylcholine or the spasm of genuine asthma. From the present experiments with induced bronchospasm it is not possible to distinguish different types, except that they develop with different speed.

The strongest antihistamines, if used in sufficient dosage, are able to suppress induced bronchial obstruction if it is mild—e.g., if it does not depress the vital capacity by more than approximately 30%. If a severe attack is induced the protection becomes partial or fails altogether. This is in accord with clinical experience. I have never seen an acute asthmatic attack influenced by an antihistamine. The failure to abolish any bronchial obstruction completely can also be seen if the effect of the antihistamines is compared with the effect of isopropylnoradrenaline, as seen in Figs. 3 and 4. When in some of these experiments pyribenzamine gave partial relief, aleudrine quickly restored the vital capacity to normal. This partial action may be comparable to the results of Bain (1949), who could not abolish the histamine effect on the skin completely with antihistamines.

It must be emphasized that the dosage of phenergan used in the induced attacks varied greatly—from 25 to 75 mg.—and that in one case I was not able to suppress a mild attack caused by acetyl-β-methylcholine chloride. Pyribenzamine used as aerosol had a definite effect in some cases but not in others. This confirms the experience that none of these substances is effective in every subject. Some patients are sensitive to one but not another, and so far it has not been possible to predict whether a given substance would be effective in a particular patient.

As the experimental evidence is definite it seems strange that some observers should have had negative clinical results (Hunter and Dunlop, 1948 ; Southwell, 1948 ; Dunlop and Hunter, 1948). Their method was not completely satisfactory, as I have pointed out before (Herxheimer, 1948b). The patients were unselected, and the dosage was uniform and rather low. Under such conditions a small proportion of successes may be expected, and it will not differ much from the pseudo-successes achieved by the natural vagaries of the disease and by suggestion.

I have described some effects of anthisan (1948a), and the North American literature contains numerous reports of so-called clinical successes. The percentage of cures reported is usually much smaller than in urticaria or hay-fever, and the assessment of clinical success is indefinite. Our clinical experience shows that the stronger antihistamines (and in some cases benadryl) have a beneficial effect on those patients who are sensitive to them. They do not help at all in severe attacks and in those acute attacks which develop after a long interval of freedom. They are excellent in the mild and moderate chronic asthmatic state (for instance, *after* acute attacks), although they do not abolish the disease completely.

Two criticisms of the present series must be considered. One is that the beneficial action of the antihistamines in asthma is due to their sedative influence. There is no doubt that these drugs have a sedative action, but it is distinct from their antispasmodic property. I have attempted to obtain the same anti-asthmatic effect with large doses of phenobarbitone, up to 2 and 3 gr. (130–195 mg.), but without success. The patient feels very tired, but is still awakened by the attacks. The soporific effect of anthisan and phenergan wears off to some measure after four or five days' use, but the antispasmodic effect persists. Some patients do not experience a soporific effect at all, and in spite of this the antispasmodic effect is present.

The other criticism is that the beneficial effect is due to suggestion. It is certain that asthmatic patients respond to suggestion more readily than normal persons. But in my patients many different drugs were tried in different dosages, and it usually happened that one particular dosage of one or two drugs was found effective, and any change to another substance or dosage was quickly followed by a relapse. When many attempts have been made at treatment the asthmatic patient is no longer deceived by suggestion. Even if many of the beneficial results were due to suggestion this could not be the explanation of the experiments with induced bronchoconstriction in normal and asthmatic subjects.

I have come to the conclusion that the antihistamines constitute a definite improvement in our treatment of some kinds of chronic asthma. They are the best agents we have for night-time administration, and, if they are combined with ephedrine in the daytime and aleudrine (isopropylnoradrenaline) or aminophyllin to cut short acute superimposed attacks, the success achieved is worth the laborious process of determining the optimum dosage, which may require weeks of patient observation. The practitioner may feel that this will be difficult ; but our experience is still very small, and it may well be that more effective substances and simpler ways of applying them will be found. In any case, it would be a grave error to add the antihistamines to the vast rubbish-heap of anti-asthmatic remedies which have been found wanting.

Summary

Phenergan and anthisan suppress mild bronchial spasm in humans induced by histamine, acetyl-β-methylcholine chloride, and allergenic extracts.

Severe attacks so induced could not be suppressed. There is no evidence that oral doses of these substances suppress acute severe attacks of genuine asthma.

Clinical evidence suggests that the stronger antihistamines are of great value in the mild and moderate asthmatic state, especially during the night. In this condition they can be conveniently combined with day doses of ephedrine and, if necessary, aleudrine in order to check acute exacerbations. The wide variation of the response makes it necessary to try out the antihistamine and its dosage individually.

A CASE OF TOXOPLASMOSIS*

BY

A. B. NUTT, M.B., B.S., M.Sc., F.R.C.S.
TREVOR WRIGHT, M.D., D.C.H.
J. H. BOWIE, M.B., Ch.B.

AND

C. P. BEATTIE, M.B., Ch.B., D.P.H.

(From the Children's Hospital, Sheffield, and the Bacteriology Department, University of Sheffield)

An annotation in the *British Medical Journal* of April 23, 1949 (p. 718), reviews toxoplasmosis and gives references to important contributions to our knowledge of this disease. A paper by Callahan, Russell, and Smith (1946) and Binkhorst's (1948) book may also be found useful by those interested in the subject. As is stated in the annotation, the first case of congenital toxoplasmosis recognized in this country was described by Jacoby and Sagorin (1948). At the time when their report was published we were investigating another case, which we now put on record.

Case Report

The patient, a girl aged 4, was born normally at full term ; weight 6 lb. 5 oz. (2.86 kg.) The neonatal period was uneventful—no jaundice, anaemia, haemorrhagic phenomena, or respiratory distress—and during the first year she was regarded by her mother as normal, having no illness, feeding difficulties, skin rashes, diarrhoea, or vomiting. At 18 months of age her parents noticed that she was partially blind and had a squint. She was clumsy in her gait and had a tendency to fall over objects placed in her way. Apart from this she was in good health

*Read in the Section of Ophthalmology at the Annual Meeting of the British Medical Association, Harrogate, 1949, by Mr. A. B. Nutt.

and was able to walk and play and to pick up objects when she dropped them.

Her mother, father, sister, aged 5, and brother, aged 2, are alive and well. No abnormality can be found in their eyes, and their mental development is normal. There is no history of tuberculosis or syphilis in the family. The mother has had three normal pregnancies and no miscarriages, and she has no recollection of any illness, even slight or transitory, during any of the pregnancies.

Because of her difficulty in seeing and her squint, the patient at 18 months was brought to see one of us (A. B. N.). Examination of the fundi at that time revealed a choroido-retinal scar involving each macula. She was kept under observation, but it was not until June, 1948, that the possibility of toxoplasmosis was considered on account of the clinical similarity of her condition to that of cases seen in Geneva with Professor Franceschetti and Dr. Bammatter.

On October 20 she was admitted to hospital for more complete investigation. At that time she weighed 37 lb. (16.78 kg.). Nothing of consequence was found in the general physical examination. The results obtained by cytological and biochemical examination of the blood, cerebrospinal fluid, and urine were within normal limits; the Wassermann reaction and the Kahn test on the blood were negative. Certainly, however, the child was mentally retarded.

The visual acuity could not be accurately determined; obviously it was low centrally, but it was good enough peripherally for the child to distinguish large objects. There was a left convergent strabismus and a searching nystagmus. The anterior segment of each eye was normal and the pupils reacted to light both directly and consensually, but the reaction was sluggish.

In the right eye there was slight pallor of the disk, but the retinal vessels were of normal calibre. There was a large oval macular scar measuring 4 D.D. horizontally and 2½ D.D. vertically (Fig. 1). The edges were fairly well defined. The inner half of the area showed choroido-retinal atrophy with little or no pigment, but in the outer half there was gross pigmentary

Fig. 1

disturbance surrounding an area in which choroidal vessels could be seen.

In the left eye there was an advanced degree of optic atrophy, with some attenuation of the retinal vessels. The temporal margin of the disk was obscured by a slightly elevated, possibly glial, mass, on the surface of which there was fine pigmentary disturbance. There was an extensive choroido-retinal scar (Fig. 2). It consisted of a central portion more or less circular in shape and approximately 2 D.D. across. This was joined to a larger and more temporal scar by a short, narrow isthmus of choroido-retinal atrophy traversed by a large choroidal vessel. The larger scar was triangular in shape, the sides being about equal in length, the apex pointing to the periphery in the

Fig. 2

horizontal meridian and the base towards the disk. Each side of the triangle measured about 3 D.D. The edges of the whole scar were sharply defined. The white sclera was widely exposed and a number of large choroidal vessels could be seen running across its base.

There was fairly gross pigmentary disturbance, especially in the temporal portion of the scar, and both showed connective-tissue proliferation.

Serology

The patient's cerebrospinal fluid was examined for toxoplasma, but without success. Sera from the patient and from other members of her family were then examined for the presence of toxoplasma-neutralizing antibodies by intradermal tests in rabbits as described by Sabin (1942). The first test, carried out with fresh serum from the patient (not shown in the following Table), indicated that it neutralized a 1:10,000 dilution. This Sabin interpreted as equivocal, and recommended that the test should be repeated. This was done, and sera from other members of the family were also tested, with the following results.

Subject	Age (Years)	Date of Test	Serum	Size of Skin Lesions produced by Dilutions of Toxoplasma Suspension Mixed with Serum Under Test			
				1:20	1:100	1:1,000	1:10,000
Patient	3¾	19/11/48	Fresh	+++	+++	+	0
Mother	27	,,	,,	+++	+++	++	0
Sister	5	,,	,,	+++	+++	+++	++
Father	36	14/1/49	,,	+++	+++	+++	++
,,	,,	21/1/49	Freeze-dried	+++	+++	++	+
Brother	2	14/1/49	Fresh	+++	+++	+++	+
,,	,,	21/1/49	Freeze-dried	+++	+++	+++	+
All controls				+++	+++	++	+

The accompanying Diagram shows the size of the skin lesions produced in the rabbit. Comparison of the control series (dilutions of toxoplasma suspension without serum) with the test series (dilutions of toxoplasma suspension to which was added serum from the patient) will show the extent to which her serum neutralized the toxoplasma. These results suggested the presence of toxoplasma antibody in the serum of the patient and her mother. Freeze-dried specimens of their sera and of the serum of the sister were sent to Dr. Sabin, who very kindly examined them by his dye-test method (Sabin and Feldman, 1948) and by the complement-fixation method. He reported as follows:

	Dye Test (Titre)	Complement-fixation Test (Titre)
Patient	1:1024	1:10
Mother	1:32	1:4
Sister	0	0

Sabin considered that these results supplied strong evidence that the disease from which the patient suffered was congenital toxoplasmosis. The titre in the mother he thought rather lower than is sometimes found four years after infection.

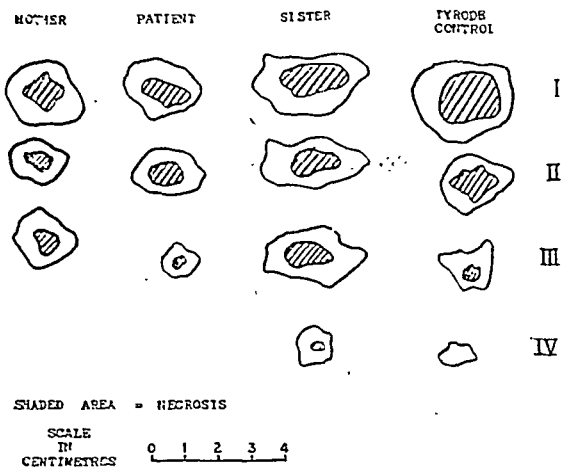

Diagram showing tracings of skin (rabbit) neutralizing test for toxoplasmosis. Final dilution of toxoplasma suspension I, 1 : 20; II, 1 : 100; III, 1 : 1,000; IV, 1 : 10,000.

Discussion

In 1942 a group of 151 cases was investigated by Sabin, employing the toxoplasma-neutralizing antibody test. He found that not only did the infants and children showing the now well-recognized tetrad (convulsions, internal hydrocephalus, intracerebral calcification, and choroidoretinitis) and their mothers give positive reactions for the toxoplasma, but so also did other varied types of case. These were mothers who had given birth to anencephalic monsters, older children and adults with chorioretinitis of unknown aetiology, some unexplained cases of encephalitis, and children and adults who had congenital cataract and other disturbances of the eyes. The above findings are quoted as a reminder that infection with the toxoplasma may produce a very varied clinical picture, including isolated disorders of the eye in which previously the aetiology was said to be obscure or simply congenital.

As regards the ocular findings in toxoplasmosis, Binkhorst (1948) found focal retinal lesions in all his cases, and he suggests that chorioretinitis may sometimes be the only clinical manifestation of this infection. He considers that for the clinical diagnosis of toxoplasmosis ophthalmoscopic examination is indispensable.

In 1942 Cowen, Wolf, and Paige reported six cases of toxoplasmosis, in all of which the outstanding features were ocular abnormalities such as chorioretinitis, microphthalmos, and strabismus. The ocular signs in toxoplasmosis have been carefully studied and recorded by Koch, Wolf, Cowen, and Paige (1943). The fundus lesions are predominantly bilateral, focal, and multiple. The macular region is invariably involved, and, less often, the periphery. The earliest change is localized oedema of the retina. The ultimate scar has a punched-out appearance, and there is extensive choroido-retinal degeneration together with connective tissue and pigment proliferation, the rest of the retina remaining normal in appearance during all observed stages of the infection. Optic atrophy seems to be the rule.

The case reported above was first brought for medical advice because the mother noticed the child's clumsy movements and suspected defective vision. To the mother the child appeared otherwise quite normal. It should be stressed that the main features of the case were ophthalmic in their presentation. It was only on closer examination and on watching the progress of the child that mental retardation was recognized. This latter is certainly more than could be attributed to defective vision.

Intracerebral calcification has been found post mortem or detected by radiography in most cases of congenital toxoplasmosis. The finding, however, does not seem to be specific or essential for the diagnosis, and this impression is confirmed by Binkhorst (1948), Adams *et al.* (1948), and Sabin (personal communication). The last-named, however, has had only one other case in which intracerebral calcification was absent.

Admittedly a diagnosis of toxoplasmosis is clinched only by isolation of the toxoplasma. At the same time it is felt that the clinical picture in this case, combined with the serological results, warrants the diagnosis of congenital toxoplasmosis. It is inferred that the infection was acquired *in utero* from the mother, as her serum gave a positive result in the neutralizing antibodies tests. An interesting point is that the patient's sister, aged 5, showed no evidence of antibodies, nor did the brother, aged 2. This suggests the possibility that the mother's infectivity may have been limited to a period within three years.

Summary

A case of congenital toxoplasmosis is described in a girl aged 4 years.

The main clinical features are defective vision with a searching nystagmus, bilateral chorioretinitis, and mental retardation.

Evidence in favour of the diagnosis is supported by the toxoplasma-neutralizing antibody test, the dye test, and the complement-fixation test.

Ophthalmoscopic examination would seem to be important for the clinical diagnosis of toxoplasmosis, and evidence of choroido-retinal disturbance should be looked for in all children with a history of convulsions, hydrocephalus, and mental retardation.

In order to help build up the National Hospital Service Reserve, which will provide an organization of trained men and women in the event of war to meet the needs of expanded hospital services, the Ministry of Health has asked local authorities to provide at civil defence corps recruiting centres facilities for officers of the St. John Ambulance Brigade and the British Red Cross Society to recruit auxiliary members of the reserve.

CHLORAMPHENICOL IN TYPHOID FEVER

A PRELIMINARY REPORT OF CLINICAL TRIAL IN 6 CASES

BY

J. C. PATEL, M.D., Ph.D., M.R.C.P.
D. D. BANKER, M.D.

AND

C. J. MODI, M.B., B.S.

(*From King Edward Memorial Hospital, Bombay*)

Chloramphenicol (chloromycetin) is a new antibiotic derived from a soil streptomyces known as *Streptomyces venezuelae*. It was first isolated for therapeutic purposes by Ehrlich and his associates in 1947.

The first report of the beneficial effect of this antibiotic in typhoid fever came from Woodward and his co-workers in Malaya in 1948. Since then the drug has been given a trial by many workers in different parts of the world. Murgatroyd (1949) has tried it in one case in London. A controlled trial is in progress in the United Kingdom as a result of the recent Berkshire outbreak (Bradley, 1949). In India the drug has been tried in typhoid fever by Shah (1949) and by Vakil (1949).

The diagnosis of typhoid fever may be open to doubt in many of the cases of these two Indian authors. Shah's series of 33 cases contains only eight with positive blood cultures, and Vakil does not mention the number of cases in which blood culture was positive in his series of 14. Neither of these authors mentions previous T.A.B. inoculation in their cases.

Method

We have tried the drug in the clinical investigation ward of the King Edward Memorial Hospital in six cases—three males and three females, all being adults. Details of these cases are given in the Table. In all of them blood culture was positive, the Vi phage types of *Salmonella typhi* isolated being "A" in three cases, "E_1" in one case, and ? (untypable) in two cases. These six cases were encountered during a period extending from the latter half of May to July, 1949. Typhoid fever being endemic in Bombay, it was not possible to collect all the cases from the same outbreak. The cases came from widely scattered parts of the city and from different walks of life: two were peons, one a hotel worker, one a nurse, and two were performing domestic duties. None gave a history of contact. In all probability the source of infection was different in each case (also compare the phage types, see above). None of the cases had previously been inoculated with T.A.B. vaccine. Five cases were severely toxic before the treatment was started and one was moderately toxic. Two of the cases (Nos. 2 and 5) had received previous type-specific parenteral phage therapy without any demonstrable benefit.

All the six cases were observed in the investigation ward meant for treatment of typhoid cases alone. Hence all the patients received the same general nursing and dietetic treatment (Patel *et al.*, 1947), the administration of the drug being the only controlled variable.

Chloramphenicol was started in the second week in one case, in the third week in three cases, in the fourth week in one case, and in the fifth week in one case. In the last two cases the drug was tried during a clinical relapse. The dosage schedule was uniform in all cases: 1 g. initially followed by 1 g. one hour later and 0.25 g. two-hourly day and night until temperature was normal for 48 hours. Then 0.25 g. three-hourly for the next 48 hours, and finally 0.25 g. four-hourly till a total dosage of 18 g. was given. However, only one case (No. 2) could be given the full 18 g. The response was dramatic, the temperature touching normal in 36 hours and remaining normal.

Owing to short supply the other two cases that recovered (Nos. 5 and 6) received 12 g. and 16 g. respectively. Both of them responded very well, the temperature coming down to normal in 24 and 48 hours respectively, but the former case relapsed after an afebrile period of 12 days. This might probably indicate that 12 g. was an inadequate dose. During this relapse *Salm. typhi* were again isolated from the blood. As chloramphenicol was unobtainable the relapse could not be treated with it.

The other three patients died. They received chloramphenicol orally for 48, 26, and 40 hours respectively, the amount of drug given being 8, 5.5, and 6 g. respectively.

Case 1 received 8 g. of chloramphenicol in 48 hours. This patient should have at least started responding (cf. Bradley, 1949: in nine treated patients the signs of resolution were obvious within 48 hours—i.e., after the administration of 8 g. of the drug), but she rapidly developed peripheral vascular failure and died. Owing to her early death No. 3 apparently received inadequate dosage. In Case 4 the patient developed a rigor about 24 hours after starting the treatment. She went into hyperpyrexia and died 16 hours later.

Table Giving Various Data of Six Cases

Case No.	Age and Sex	Vi Phage Type	Previous Specific Treatment	Initial Toxicity	Day of Disease on which Treatment Started	Duration of Treatment	Total Dosage	Temperature Normal in Hours	Toxic Reactions	Result	Comment
1	25 F	A	Nil	Severe	28th	48 hours	8 g.	—	—	Died	Case of clinical relapse with bacteriaemia
2	23 M	?	Parenteral phage therapy	,,	35th	6½ days	18 g.	36	—	Cured	,, ,, ,,
3	38 M	?	Nil	,,	11th	26 hours	5·5 g.	—	—	Died	Probably chloramphenicol did not get a chance to act
4	24 F	E_1	Nil	,,	17th	40 ,,	6 g.	—	Rigor	,,	Patient went into hyperpyrexia and peripheral vascular failure
5	20 F	A	Parenteral type-specific phage therapy	Moderate	19th	70 ,,	12 g.	24	—	Cured	Dramatic response in a phage failure case. Relapse after an afebrile period of 12 days
6	25 M	A	Nil	Severe	15th	6½ days	16 g.	48	Erythemo-papular rash	,,	Rash disappeared in 3 days

Results

In all the three cases that recovered the temperature fell by crisis or rapid lysis in 24–48 hours. This is the usual experience of other workers in most of their cases. In all these three cases the constitutional improvement was

striking and was seen earlier (within the first 24 hours) than the fall in temperature. Woodward *et al.* (1948) had a similar experience. Shah (1949), however, finds just the reverse thing. In his opinion the effect on the toxic state is slower than the effect on fever. The fall in temperature occurs in two stages (Murgatroyd, 1949 ; Vakil, 1949). An initial fall is followed by a rise, the temperature then subsiding gradually. This was seen in two of our cases.

Toxic Reactions.—Chloramphenicol seems to be non-toxic for all practical purposes (Murgatroyd, 1949 ; Shah, 1949 ; Vakil, 1949). One of our cases developed a transitory erythemo-papular rash, mainly on the trunk. A similar finding has been noted by Shah in one case. The rigor that occurred 24 hours after the beginning of treatment in Case 4 may not have been a symptom of drug toxicity. It could well have been a hyperpyrexial reaction during the course of the disease, or it may have been due to rapid lysis of a large number of organisms. It is only tentatively included here, because it has not been observed by other workers. Shah found signs of cerebral irritation in seven cases. We did not come across any other toxic reactions, neither did Woodward *et al.* However, Shah and Vakil attribute nausea, anorexia, diarrhoea, circulatory failure, oliguria, and retention of urine in some cases to chloramphenicol. The cause of death in Case 1 in the present series was circulatory failure, but whether this was due to the drug or the disease it is difficult to say. Vakil describes a tendency to leucopenia.

Relapse.—One of our cases (No. 5) relapsed after chloramphenicol therapy and after an afebrile period of 12 days. The blood culture became positive during the relapse.

Vakil has noticed relapse following chloramphenicol therapy in two cases, and Shah found one relapse in his blood-culture-positive cases and four cases of relapse if his whole series of 33 cases is considered. In three of Shah's cases the relapse occurred during maintenance therapy and in one case after an afebrile period of nine days. Woodward *et al.* found that in the doses used chloramphenicol did not prevent relapses. He came across relapses with bacteriaemia in two cases after an afebrile period of 10 and 16 days. Both responded to a second course of the antibiotic. The organisms isolated during these recurrences were as sensitive to chloramphenicol as before. Shah's cases, too, responded to further chloramphenicol therapy.

Complications.—It has been shown by Woodward *et al.* that chloramphenicol does not prevent intestinal perforation and haemorrhage even in the afebrile period of the disease. After treatment with it one of his cases developed intestinal perforation on the second day of normal temperature, and another case had massive intestinal haemorrhage on the fourth day of normal temperature. Such complications were also encountered by Vakil. In our small series we have not come across these complications.

Duration of Fever After Institution of Chloramphenicol Therapy.—The average duration was 3.5 days with Woodward *et al.* and 1.5 days in our cases. The average duration of the afebrile course of the disease was approximately 12.5 days, whereas in Woodward's control group it was 35 days.

Urine Cultures.—The urine cultures before, during, and after chloramphenicol treatment have been found to be consistently negative by Woodward *et al.* The urine cultures were not done in the present series.

Stool Cultures.—Positive stool cultures after chloramphenicol therapy are well known (Woodward *et al.*, 1948 ; Murgatroyd, 1949 ; Rumball and Moore, 1949). Murgatroyd's case had a stool culture positive for *Salm. typhi* after the course of chloramphenicol. Woodward *et al.* found positive stool cultures in two cases ; later these became negative. Rumball and Moore treated a 9-year-old chronic faecal typhoid carrier with 30 mg. chloramphenicol per kg. of body weight (i.e., three times the therapeutic dose) for seven days, and the boy still continued to pass typhoid bacilli in the stools. This was surprising in view of the fact that *Salm. typhi* are inhibited *in vitro* by 0.25 μg. of chloramphenicol per ml., while in the usual therapeutic dose the blood level attained is 40–80 μg. per ml. (Woodward *et al.*, 1948).

Blood Culture.—With chloramphenicol therapy the blood cultures become sterile, but turn positive during a relapse. This is what we observed in Case 5.

Comment

Our series is too small for any statistical evaluation of the drug ; neither is the series ideal for such a purpose, because in none of the cases was the treatment started in the first week. We agree with Bradley (1949) that the advantages of chloramphenicol cannot be fully explained or exploited until the effect on cases in the first week of the disease is measured. It may be mentioned that Shah has tried chloramphenicol in six blood-culture-positive cases (out of his series of 17 cases). In four of these the treatment was started in the first week. All these cases have recovered dramatically and without any complications following on it. Chloramphenicol is more effective in typhoid fever than aureomycin, and that, too, in a smaller dose per kg. of body weight (Patel *et al.*, 1949). We believe that the drug is the most effective therapeutic agent available at present against typhoid fever.

Summary

Six culture-positive typhoid cases treated with chloramphenicol are reported.

It is plain that chloramphenicol strikingly alters the course of typhoid fever by exerting a specific therapeutic action. However, an extensive controlled trial is necessary to determine the optimal dose.

The Cerebral Palsy Unit at Queen Mary's Hospital for Children, Carshalton, Surrey, was opened in January, 1943, and was the first of its kind in Great Britain. There has since been set up an "advice clinic" at the Lambeth Hospital, where cases of cerebral palsy are assessed from the point of view of suitability for treatment and where parents and relatives are given advice about the management of cerebral palsied children. A booklet has now been produced presenting advice to parents and others on daily treatment, schooling, rest, speech, and other points. The booklet, which is well produced, contains a number of black-and-white sketches and gives useful information in the form of question and answer. Copies may be obtained from the hospital at Carshalton (price 1s.).

PNEUMOCOCCAL MENINGITIS OF REFRACTORY TYPE TREATED BY REPLACEMENT OF C.S.F. WITH PENICILLIN

BY

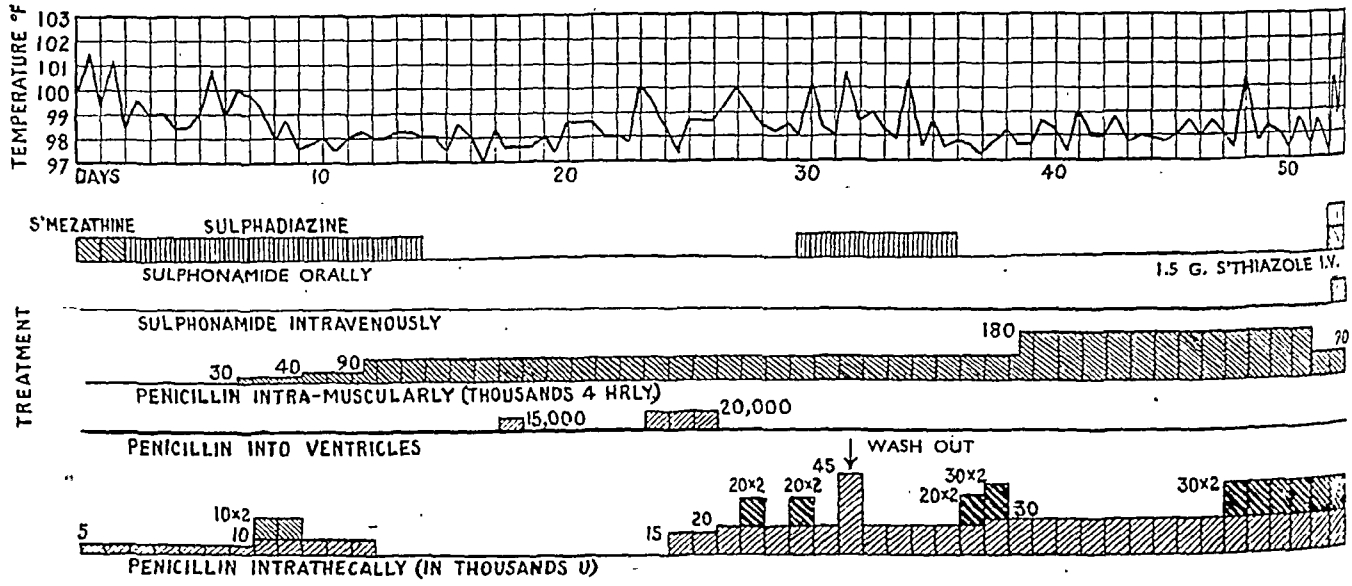
ALASTAIR ARNAUD REID, M.B., B.S.

Resident Medical Officer, Cornelia Hospital, Poole, Dorset

Does the pneumococcus develop resistance to penicillin? It would seem from a study of the following case that it does, although such resistance has not, so far as I know, hitherto been noted.

Case Report

The patient, a female child aged 13 months, was admitted to hospital as a typical case of bronchopneumonia, which responded in three days to a combined course of sulphamezathine and penicillin. She then appeared to be well for a fortnight, but at the end of this time the pneumonia recurred and did not respond to treatment.



Twenty-four days after the beginning of the illness slight neck stiffness was noted and was thought to be due to meningism. Nevertheless, a lumbar puncture was performed and C.S.F. under normal pressure was withdrawn. Contamination with blood precluded its immediate examination, but a typical culture of encapsulated lanceolate diplococci was obtained, giving a diagnosis of pneumococcal meningitis. Later examination of the C.S.F. confirmed this. The organisms were tested against penicillin and were found to be moderately sensitive. (The test used was a modification of the filter-paper method which was in vogue at that time. On this occasion the strain was inhibited by a concentration of 5–10 units of penicillin per ml.) Lumbar puncture was immediately repeated, turbid fluid under increased pressure was withdrawn, and intrathecal penicillin therapy was begun, details of which are given in the Chart. (The days are numbered from the beginning of treatment for meningitis.) On the fifth day neck stiffness had almost disappeared and the C.S.F. was found to be nearly normal, as judged by the glucose level, which experience showed to be the most sensitive index to the state of the infection, and the first figure to be affected by either an increase or a decrease in its severity.

On the sixth and seventh days, however, relapse occurred in spite of treatment. Neck stiffness became pronounced and the fluid again became turbid. Sensitivity of the organism to penicillin *in vitro* was now found to be slight (growth inhibited by 10–20 units per ml.). Accordingly the dosage was increased, 10,000 units being given intrathecally twice daily. The results were dramatic, for in less than 72 hours the C.S.F. was quite clear. The sugar had returned to normal, but there was still some neck stiffness. Improvement continued until the 18th day, when the C.S.F. again became cloudy, with an increased cell count. It was decided that, as penicillin given by lumbar puncture was unlikely to inhibit organisms in the exudate at the base of the brain, the drug should also be given into the ventricles so that it could penetrate with the C.S.F. every part of the circulation. This was done, with some improvement.

It was felt, however, that it was possible that once the penicillin in the C.S.F. had been brought to a high level it could be maintained by heavy intramuscular doses. That this was probably correct is shown by the fact that improvement was maintained for some days by intramuscular dosage alone, until unfortunately, by a mischance, the intramuscular penicillin was stopped one evening. Next morning the meningitis had recurred in a severe form with tooth-grinding and neck stiffness. The C.S.F. was turbid and teeming with encapsulated pneumococci, which were now said to be completely resistant *in vitro* up to 25 units of penicillin per ml. (24th day).

However, as the Queckenstedt test was normal and as indigo carmine injected into the ventricle appeared at lumbar puncture next day, thus demonstrating patency of the system, it was decided to resume intensive treatment (24th day). This produced some improvement, but on the 28th day, in view of the sharp drop in the sugar, it was decided that the only hope lay in more drastic treatment.

Both clinically and *in vitro* the resistance of the organism had appeared to rise, necessitating repeated increase in the dosage of penicillin. As strong solutions of penicillin are irritant it was decided that the only practicable thing to do was to replace the infected C.S.F. with penicillin solution of a safe concentration. It was thus hoped to spread the penicillin as evenly as possible over the whole system.

Consequently, on the 32nd day simultaneous puncture of the right ventricle and the lumbar region was performed. Indigo carmine (3 ml.; 1%) was injected by the lumbar needle to serve as a marker, and it was followed by 45 ml. of penicillin solution (1,000 units per ml.). The dye appeared through the ventricular needle and both needles were then withdrawn. There were no ill effects from the operation and great improvement in the C.S.F., the sugar rising sharply in spite of the dilution by saline. The cells increased greatly (see Table), but as all were old and degenerate it was almost certainly due to the "stirring up of the mud" all the way up the cord and the base of the brain.

Table Showing Cell and Sugar Content of C.S.F.

Day	Cells per c.mm.	Sugar mg./100 ml.	Day	Cells per c.mm.	Sugar mg./100 ml.
2	1,700	39	33	2,200	75
5	610	66	35	160	78
6	280	31	37	130	70
7	1,800	33	39	280	51
9	360	92	43	65	66
12	28	65	44	290	59
18	800	59	46	140	47
24	—	25	47	20	61
27	4,000	54	50	14,560	57
28	1,000	29	52	210	65
31	100	63	53	20,000	17

Paracolon bacilli were found on days 50, 51, 52, and 53.

During the next few days the patient improved, but intensive penicillin therapy was continued in order to keep up the concentration in the C.S.F. By the 37th day the cerebral cry had quite disappeared, as had the neck stiffness. During the succeeding days, although the condition of the meningitis fluctuated, the child improved greatly. She began to resist treatment forcibly, to eat well, and to play with her toys. Up to the 47th day honours were divided between the penicillin and the organisms, although the Queckenstedt test remained normal. Repeated examination of the nose and ear by an E.N.T. surgeon again revealed no source of reinfection.

On the 53rd day, however, there was a disastrous relapse. The neck became retracted and the C.S.F. purulent and under increased pressure. Paracolon bacilli (first noted in a culture four days before) were seen in large numbers in a smear, although no pneumococci were present. In spite of double cleaning with iodine, these bacilli had presumably been introduced from the skin by the needle. The "cerebral cry" returned, and in spite of intensive intravenous sulphonamides the patient became collapsed and comatose. Convulsions developed at 8 p.m. and death came three and a half hours later. Unfortunately it was impossible to perform a post-mortem examination, invaluable as this would have been.

Discussion

The infecting organism rapidly developed an apparent resistance to penicillin *in vitro* (at least according to the tests used at that time), but it was still possible to kill it *in vivo* by means of large doses. It appeared likely that the case would ultimately have become chronic in the same way as do some cases of tuberculous meningitis treated with streptomycin, relapse occurring as soon as the drug is withdrawn. Because large doses of intrathecal penicillin were known to be dangerous, this case was at first treated too conservatively. The initial doses should have been bigger and given twice daily. If this had been done the organism might have been destroyed before it became resistant. In a case of meningitis of this severity large doses are worth the risk. The child seemed to suffer no ill effects from the use of huge intrathecal doses. It seems that it is local concentration, not dosage, which is dangerous, but it is dosage or general concentration which is important therapeutically. C.S.F. lavage and replacement with penicillin offer a reasonable method of achieving this general concentration safely, and a technique has been developed and found to be satisfactory. C.S.F. replacement had no ill effects. It is also possible, while doing this, to demonstrate with dye the patency of the foramina of Magendie and Luschka. This is important in prognosis.

Finally, it is known that penicillin is poorly excreted into the C.S.F., but it has been demonstrated clinically that large intramuscular doses can keep up the concentration once this has been achieved by intrathecal administration.

The case demonstrates the necessity for a bold approach and decision in the treatment of pneumococcal meningitis. Intensive treatment, with close observation and frequent laboratory examinations, is essential if the disease is not to become chronic, and if a final cure is to be achieved.

Summary

A case of pneumococcal meningitis is described in detail. Apparent growth of resistance to penicillin on the part of the organisms is demonstrated, and the necessity for maintaining a high concentration of the drug in the C.S.F. is shown. C.S.F. replacement therapy and its results are described, and it is shown that penicillin concentration in the C.S.F. can be maintained by intramuscular dosage. A technique for demonstrating patency of the foramina in the roof of the fourth ventricle is given.

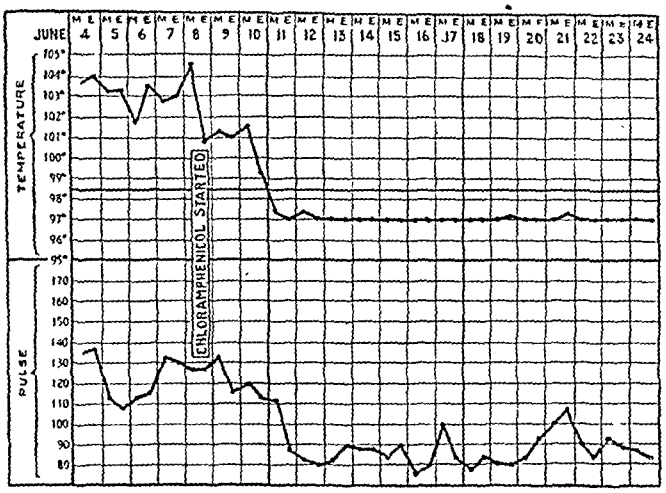
Acknowledgments are due to Dr. C. Adamson, of Durham County Hospital, for permission to publish the case, and to Mr. P. O. D. Hopps for his invaluable work in the laboratory.

Medical Memoranda

Chloramphenicol in Typhoid Fever

In view of preliminary reports of cases of typhoid fever treated by chloramphenicol (chloromycetin) (Bradley, 1949: Murgatroyd, 1949), it is considered that publication of the following case may be of interest.

Case Report



A Service patient aged 20 was admitted to hospital on June 4, 1949, with a provisional diagnosis of typhoid fever. Preventive inoculation with T.A.B. was reported to have been given in February, 1949.

He had sailed from Port Said on May 21 and first felt unwell on May 26, complaining of headache, vomiting, and sore throat. He disembarked at Southampton on May 31 and travelled by train to his home in Nottinghamshire. He still complained of frontal headache, had several rigors, and also complained of marked generalized weakness. On June 2 he had epistaxis, and on the following day was admitted to the medical ward of a general hospital for P.U.O. A few papules were noticed on the abdomen on June 4, and he was transferred to an isolation hospital. There was no history of constipation or diarrhoea.

On admission his temperature was 104° F. (40° C.), pulse 138, and respirations 26. He was mentally confused, answered questions slowly, and had difficulty in pronouncing words. There were a dozen rose-coloured spots on the front of his abdomen, which was distended but resonant. The spleen was not palpable. There were no other physical signs except a coarse bilateral nystagmus which was congenital. His condition deteriorated until on June 6 he was comatose and could not be roused. The eyes were sunken, the tongue was covered with a brown fur, and there was muttering delirium with purposeless picking at the bedclothes. The rash was heavy on the chest and buttocks, and there was retention of urine. Constipation was marked, and it continued throughout the illness. The white cell count was 6,000 (polymorphs 78%, lymphocytes 19%, eosinophils 2%, and monocytes 1%). No abnormal red or white cells were found, and films showed no malaria parasites. The urine was sterile, but a non-lactose-fermenter was grown on blood culture.

On June 8 the pulse was irregular and he showed signs of hypostatic pneumonia. At this stage a supply of chloramphenicol was obtained and an initial dose of 16 capsules (4 g.) was given by nasal tube. This was followed by six capsules (1.5 g.) with glucose twice daily for four days. Two days after treatment was started there was such a remarkable improvement in his condition that he was able to swallow capsules and fluids normally and to answer questions, although his speech was slurred and indistinct. On the following day (June 12) temperature, pulse, and respirations had returned to normal (see Chart) and he asked for food and permission to

walk round his bed. Chloramphenicol was continued with a dosage of three capsules twice daily for a further week, making a total dosage of 33½ g. He made an uninterrupted recovery except for slight hoarseness of voice lasting two days, and when seen in August he was feeling very well and had regained his usual weight.

Bacteriological Results.—June 4:—Supplementary report from Salmonella Reference Laboratory: Blood culture organism has the following antigenic structure: O = IX, XII (Vi); H=d. Therefore it is *Salmonella typhi*. Dr. Felix, Central Enteric Laboratory, reported that the culture belonged to an untypable Vi strain (degraded). June 8: Faeces positive for *Salmonella typhi*. The patient's serum gave a positive agglutination with this organism to a titre of 1/250. June 14:—Blood Widal test: *Typhosus*, H −, O 1/250; *paratyphosus A*, H −, O 1/500; *paratyphosus B*, H −, O 1/250.

Three subsequent specimens of faeces and urine showed no pathogens, and he was discharged from hospital in excellent health on July 7. A subsequent examination of faeces on August 11 was negative for organisms of the enteric group.

Staphylococcal Portal Pyaemia

This condition has a grave prognosis, and before the introduction of penicillin was nearly always fatal. In the following case a severe infection of several weeks' duration was cured by combined penicillin and sulphonamide therapy.

CASE REPORT

The patient, a fitter aged 31, was referred to hospital with a diagnosis of *infective hepatitis*. His illness had apparently commenced three weeks previously with complete loss of appetite followed by severe upper abdominal pain, constipation, and vomiting. A few days before admission he noticed his urine was dark and his faeces pale. Before this illness the patient had been troubled with recurring carbuncles of the skin, but had not received any chemotherapy. The last one occurred on the buttock and had healed two weeks before his present symptoms began. He had served in the Middle East during the war and gave a history of several attacks of malaria, but none of dysentery.

On examination he was pale and thin. Icterus was observed in the conjunctivae but not in the skin. The temperature was 100.4° F. (38° C.). There was epigastric tenderness, but no enlargement of the liver or spleen, and no ascites. The urine showed a trace of bile.

The patient's temperature rose the following day to 102° F. (38.9° C.), and thereafter exhibited a daily swing from 99 to 103° F. (37.2–39.4° C.). Blood count showed: haemoglobin 83%; white cells 31,800 per c.mm. (polymorphs 91%, lymphocytes 7%, monocytes 2%). The clinical picture was unlike that of infective hepatitis, which view was supported by the results of liver function tests (thymol turbidity, 1 unit; thymol flocculation, 0; alkaline phosphatase (Jenner and Kay) 19.2 units). His condition deteriorated rapidly. The jaundice became deeper, and was apparent in the skin as well as the conjunctivae; the liver became tender and enlarged to four finger-breadths below the right costal margin. The abdominal pain was almost constant and became very severe. The haemoglobin fell to 66% and the white cells increased to 41,000 per c.mm. The patient was now dehydrated, thin, and desperately ill. He vomited on several occasions and had severe anorexia.

One week after admission he complained of pain in both shoulders, and these joints became swollen, hot, and painful to move. The diagnosis of pyaemia with multiple liver abscesses and suppurative arthritis of the shoulder joints then became apparent, and was confirmed by a blood culture. The organism was a penicillin-sensitive *Staphylococcus aureus*. A few days previously a needle biopsy of the liver (performed by Dr. H. A. Dewar) showed infiltration of the portal tracts with polymorphs. A fluoroscopic examination did not show any elevation or restricted movement of the diaphragm.

Penicillin, one million units daily, was started on the tenth day after admission. After three days the evening temperature was still 102° F. (38.9° C.). The next day sulphamezathine was added; the temperature fell rapidly to normal and the patient's condition improved dramatically. His appetite returned, the jaundice faded, and the liver diminished in size and lost its tenderness. He began to put on weight and became lively and cheerful. The penicillin was continued for ten days and the sulphamezathine to a total dosage of 40 g. The swelling and pain in the left shoulder joint subsided, but the right shoulder remained painful and stiff. There was no radiographic bone or joint change. The affected joint was treated by immobilization in a sling for three weeks, followed by exercises and heat. During this time the patient showed a steady improvement and the temperature did not rise above normal. He was discharged after a month in hospital.

Six weeks later he was feeling well and was free of symptoms, apart from some residual stiffness in the right shoulder.

COMMENT

The diagnosis of pyaemic abscesses of the liver was assisted in this case by the development of metastatic arthritis in the shoulder joints. Both lesions were complications of a systemic pyaemia which appeared to follow a carbuncle. The suddenness of the hepatic enlargement was a striking feature, and was similar to that observed by Wyndham (1945) in each of his three cases. The appearance of jaundice may be taken as an indication of the severity of the infection, for it is regarded by several authors (Rothenberg and Linder, 1934; Ochsner *et al.*, 1938; Smith, 1944) as a late and infrequent sign of ominous significance occurring only when the abscesses are multiple and widespread throughout the organ.

I wish to express my thanks to Dr. A. G. Ogilvie for permission to record this case.

Reviews

PRACTICE OF OPHTHALMOLOGY

Modern Practice in Ophthalmology, 1949. Edited by H. B. Stallard, M.B.E., F.R.C.S. (Pp. 525; 231 illustrations; 30 coloured plates; £3 5s.) London: Butterworth. 1949.

The Modern Practice series is written for the general medical practitioner as a guide when he shares with a consultant the responsibility of the conduct of a case ordinarily outside his province, or when it falls to his lot to act on his own responsibility when the consultant is not available. The present volume on ophthalmology is written by 14 well-known contributors under the general editorship of Mr. H. B. Stallard, who has written several sections himself.

A book of this type is difficult to prepare. Obviously it cannot be comprehensive, and there are few decisions requiring more judgment than the selection of the essentials and the discarding of the non-essentials. Ophthalmology presents more problems in this respect than any other branch of medicine, for it is peculiarly specialized and the effects of disease of the eye may be dramatic and catastrophic. The tendency for most books of this type is to be encyclopaedic, treating the diseases of each tissue systematically. This is the style of the present volume, and without question each section is good and its teaching reliable.

As a rule, however, disease presents itself to the general practitioner in a different way. In his experience the essential problem is to assess the importance of such questions as the significance of a red or a painful eye. The answer would be difficult to find from the present book unless the reader consulted a multitude of headings and studied the differential diagnosis of each. To take another example, a common complaint addressed to the general practitioner is that of double vision. Reference to the index leads to a description of diplopia goggles in testing for squint. There is, however, an excellent section on ocular palsies in the chapter on medical ophthalmology, a separate section on paralytic squint written from the standpoint of muscular function, while in the chapter dealing with cataract uniocular diplopia (the commonest cause of double vision in practice) is noted. This tendency is accentuated, to take a further example, in the duplication of the discussion of the vascular retinopathies and of vascular occlusions. These lesions are extensively described in the chapter on medical ophthalmology, and the discussion is repeated by a different author in another chapter dealing with diseases of the retina. Both sections are well illustrated, but there is no cross-reference to the text or the illustrations. The best chapter, from this viewpoint, is that on the cornea. The subject is treated non-compartmentally, and an account is given of the different types of corneal lesion, their main causes, the main symptoms and signs of corneal disease, the main features providing aetiological clues, what conditions elsewhere may throw light on the local lesion, the prognosis, and the general principles of treatment. The presentation of the subject-matter in this case makes it relatively easy for the practitioner (who is always assumed to have forgotten his ophthalmology) to use the book as a useful vade-mecum.

The book is well produced, and the illustrations are lavish and excellent. As is to be expected in a work of this type, most of these are not original but are derived from periodicals or other books: for the use of these the publishers have been acknowledged but not the authors—an omission which, it is hoped, will not become a practice in British medical literature.

STEWART DUKE-ELDER.

TEXTBOOK OF HAEMATOLOGY

Hematology. By Cyrus C. Sturgis, M.D. (Pp. 915; illustrated. £3 3s.) Oxford: Blackwell Scientific Publications. 1949.

An author intending to write a new general textbook of haematology must face the fact that there is already one superlatively good work on the subject—Wintrobe's *Clinical Hematology*, published in 1942. Yet it is evident that no textbook, however good, can dominate the field indefinitely. Time by itself favours the new work, because research on haematology is active and every year there is much to add and a little to take away. Moreover, many different approaches are possible, and a new publication may be welcome simply because it is written from a new viewpoint.

The strongest feature in the present book is its historical approach, and for this alone it will be a valuable work of reference. For instance, anyone trying to understand why forty years ago anaemic adolescent girls turned green, whereas now they simply turn pale, will be comforted to read Cabot's description, written in 1915: "It takes the eye of faith to see any justification for the title of the disease [chlorosis]. . . . If one exercises a great deal of imagination, one might possibly see the slightest imaginable tint of olive green in the shadow beneath the chin, that is all."

Perhaps the chief weakness of the book is its lack of interest in methods and standards; indeed, methods are not described at all, and in the first paragraph the author is content to refer to values obtained in a group of persons "in the vicinity of Ann Arbor." Nowhere is mentioned the problem of obtaining consistency between different centres in making haemoglobin estimations, or of the innumerable sources of error in haematological methods.

A book published in 1948 ought not to have to admit that "the separation of acquired . . . hemolytic anemia with acholuric jaundice [from the congenital form] . . . causes considerable difficulty." This statement ignores the fact that two methods of distinguishing between these conditions are now known: first, erythrocyte survival tests, and, secondly, the direct Coombs test. Further examples of the rather patchy treatment of recent work are as follows: no mention of the work on the anaemia of infection by Wintrobe and his co-workers; no reference to the iron-binding protein or to the Rh "blocking" antibody; no mention of the use of urethane in the treatment of leukaemia or of the advantage of adding citric acid to citrate-glucose mixtures for blood preservation.

In short, this book cannot be regarded as a first-class scientific work, but it can be strongly recommended as a very readable introduction to haematology which should prove useful to anyone who wishes to know more of the history of any particular syndrome.

P. L. MOLLISON.

THE TECHNIQUE OF TRANSFUSION

Blood Transfusion. By Elmer L. De Gowin, M.D., Robert C. Hardin, M.D., and John B. Alsever, M.D. (Pp. 587; 200 diagrams. £2 5s.) Philadelphia and London: W. B. Saunders Company. 1949.

The three authors of this book were all concerned with the organization and running of blood banks in the United States during the recent world war, and one of them was responsible for teaching the facts of blood transfusion in

the Army. During these activities they all came to feel the need for a book covering the entire field of blood transfusion, and the present volume is designed to cover this deficiency. The volume is large and certainly contains a great amount of information about transfusion, but it does not form a really comprehensive treatise on the subject. The emphasis throughout the volume is on the technical side, and the result is an admirable practical handbook. Its chief value will be for the laboratory worker and those employed in blood banks; the clinician will not find in it a readable account of the medical and surgical sides of the subject. An important feature of the book is what the authors call "a series of flow diagrams." These are marginal line drawings illustrating the steps of the various technical processes, so that the operator may acquire his technique with the least effort of the mind. The diagrams have been admirably done by the instructor in art at the State University of Iowa.

In their preface the authors deplore the fact that blood transfusion has become a minor specialty, but they believe that the necessity for this is genuine. A blood transfusion cannot be carried out simply as it used to be, though the process can be done largely by technicians. The present volume certainly produces the impression that the physicians and surgeons can now take back seats in the transfusion arena, and that the philosophy of blood transfusion is a matter of little importance.

GEOFFREY KEYNES.

RADIOLOGIST AND CLINICIAN

Confrontations: Radio-Anatomo-Cliniques. By De M. Chiray, R. A. Gutmann, and J. Sénèque. (Pp. 79; 150 figures. 1,000 francs.) Paris: G. Doin, Masson. 1949.

In this symposium from a number of Paris hospitals some forty case histories are presented in such a way as to bring together the *x*-ray appearances, the pathological anatomy, and the clinical course. About half of each page is taken up with illustrations, and the *x*-ray reproductions and pathological photographs are excellent. The quality of the case histories varies, but in most of them the reader feels he is given an insight into the way the clinician's mind worked when they were taken. Many phrases have that epigrammatic clarity which is typical of French medicine at its best, and which is so difficult to imitate in other languages. Considerable space is allotted to highly critical commentaries on the *x* rays.

As might be expected from the editors' interests, the problems are mainly gastro-enterological. However good the radiological and gastroscopical technique, it is often impossible to decide whether a distortion of the pyloric antrum is due to gastritis or carcinoma, whether a jejunal ulcer is present or not, and whether an ulcer is carcinomatous. In elderly subjects decisions on correct procedure may be fraught with anxiety, and in most clinics unnecessary mistakes probably occur in the borderland between clinical and *x*-ray responsibility. The moral of these studies is that the radiologist who takes a superficial clinical history and allows it to influence his diagnosis is a menace. Certain *x*-ray appearances make operation desirable, regardless of the diagnosis suggested by classical clinical medicine. On the other hand, the clinician cannot shift his responsibility on to the radiologist. It is his duty repeatedly to ask himself whether all the symptoms can be explained by the *x*-ray findings or whether an alternative explanation is essential. The *x*-ray department can only be as good as the clinicians allow it to be, and without the fullest collaboration mistakes and mutual recriminations are inevitable.

The value of the book lies in the cases it describes. They are too uncommon to be properly dealt with in a textbook, and too common to find a place in ephemeral journals. In addition, few textbooks or journals could afford the lavish but essential illustrations.

D. A. JENNINGS.

HYPNOSIS

Medical Hypnosis. By Lewis R. Wolberg, M.D. (Volume 1: pp. 449; $5.50. Volume 2: pp. 513; $6.50.) New York: Grune and Stratton. 1948.

These handsomely produced volumes provide an account of theory and practice in hypnosis which has been largely oriented by psycho-analytic teaching. Thus, in his interesting chapter on the nature of hypnosis the author rejects one by one theories of a neuro-physiological kind; and though he finds points of criticism in the usual psycho-analytic theory of hypnosis he finally adopts a theory which is little removed from it. Those who are not analysts will be inclined to criticize this critique. The psycho-analytic theory places great importance on the personal relationship between the hypnotist and the subject; the hypnotist becomes the "intrapsychic representative of the parent or superego." This would seem to be altogether too narrow a conception. The phenomena of hypnosis will be unintelligible until they are brought into relation with a very wide class of observations on both human and animal behaviour. The hypnosis of animals has been a frequent subject of experiment, and certainly cannot be accounted for by explanations involving the fabulous superego. Any satisfactory theory would have to be applicable to the phenomena of psychic shock, hysterical conversion symptoms, normal dissociative processes such as are seen in sleep-walking, the "miracle" cures of religious conversion, and many others, besides hypnosis itself.

In the author's view the applications of hypnosis in treatment are wide and varied, but they should always be a part of a consistent scheme of psychotherapy. He discusses the use of hypnosis for the simple removal of a symptom, as a part of non-analytic types of psychotherapy, reassurance, and persuasion, and as a technique to aid progress in psycho-analysis. Nearly every chapter of the second volume is profusely illustrated with recorded conversations between doctor and patient which effectively display the author's methods. In a final note the use of hypnosis for public displays is deplored, and the author demands protective laws which would confine the use of hypnosis to the medical profession.

ELIOT SLATER.

ADVANCES IN TUBERCULOSIS

Fortschritte der Tuberkulose-Forschung und -Behandlung. Edited by H. Birkhaeuser. Vols. 1 and 2. (Pp. 446. 45.40 Swiss francs.) New York and Basle: S. Karger. 1948.

In this account of progress in research and treatment in tuberculosis abstracts have been compiled of those items of wartime literature which "seemed to the authors, on the basis of their special knowledge, worthy of notice." There are 19 articles, unequal in value and scope, and on entirely different aspects of tuberculosis. Most of them are without comment or criticism.

The best of these articles are: H. Bloch's account of the morphology, chemical constitution, and pathogenicity of the tubercle bacillus; "Experimental Pathology and Therapy," by Noel Rist; "Collapse Therapy," by Haeberlin; and "Sarcoidosis," by Loeffler and Jaccard. The workers on sarcoidosis concluded that the condition

was marked by well-defined clinical and histological characteristics. In their opinion this did not exclude a tuberculous aetiology, nor did it favour it. That sarcoidosis can be followed by tuberculosis may be due to a special predisposition. Uehlinger's case, in which sarcoidosis was followed by fulminant tuberculous septicaemia, may support this, but in the reviewer's opinion it was a single, exceptional case. As a rule, when sarcoidosis is followed by tuberculosis the latter is ordinary in appearance and course and lesions of both conditions can be found in intimate association with each other. The authors reject the virus hypothesis. From their suggestion that sarcoidosis should be catalogued as a disease of the reticulo-endothelial system they seem to expect some compensation for our ignorance of its aetiology.

W. PAGEL.

MORGAGNI'S SYNDROME

Morgagni's Syndrome. By Professor F. Henschen, M.D. (Pp. 172; illustrated. £1 10s.) Edinburgh and London: Oliver and Boyd. 1949.

The triad of hyperostosis frontalis interna, virilism, and obesity was first described by Morgagni in 1761, and in 1936 Professor Henschen suggested the term "Morgagni's syndrome." The hyperostosis which he considers the essential component of the syndrome is found in over half the population past 70, and is a necropsy finding rather than a clinical entity, for it is often symptomless. The syndrome itself is admitted by the author to be "a not very strongly pathologically accentuated variant of the endocrine state of the woman after the climacteric." People vary widely in their endocrine equipment, and there is some doubt whether Morgagni's syndrome has yet deserved to be christened. Syndromes are born easily but die with difficulty, and the bestowal of an eponym for some reason guarantees their longevity. Until doctors are clearer in their minds about what constitutes an abnormality, and until they decide how closely abnormalities must be associated to justify their being grouped together as a syndrome, there will always be doubts about the usefulness of a label. This book says, in effect, that many elderly, fat, hairy ladies have thick fronts to their skulls and nobody really knows why.

The volume is well produced and illustrated, and the thoroughness with which this painstaking work has been done results in a complete and authoritative survey of a very specialized subject.

RICHARD ASHER.

The purpose of the series of reviews of which *The Annual Review of Microbiology* (Editor, C. E. Clifton; pp. 532; £1 16s.; London: H. K. Lewis and Co.; 1948) is the second volume is not to survey the whole field of microbiology but to select about a score of important subjects in which significant advances have been made. Each topic is the responsibility of an expert contributor, who gives a critical summary of recent research. Much of this research is of a fundamental character, and it is assumed that the reader is familiar with earlier work. These reviews are thus designed primarily for those engaged in teaching and scientific research. The present volume contains articles on bacterial and protozoal metabolism and growth factors, on antibiotics and chemotherapeutic agents, and on chemical disinfectants. Immunology is represented by reviews on the nature of antibodies and complement and the inheritance of immunity, and systematic microbiology by papers on the pathogenic streptococci, spirochaetes, and the neurotropic viruses. There are also several articles on fungi, soil, and water which are likely to be of interest to industrial and agricultural bacteriologists. The contributors have succeeded admirably in producing a concise and readable summary of the work of the last few years, without notable omissions. The extensive lists of references are particularly valuable. The book will be welcomed by teachers and others whose duty it is to keep pace with the ever-increasing volume of new knowledge in microbiology.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY OCTOBER 22 1949

FRESH LIGHT ON MALARIA

So much has been added to knowledge about the parasitology and treatment of malaria during the last decade that a total revolution of ideas has taken place. The new facts, however, have come in such a fragmentary manner, major and minor discoveries jostling each other, that at times they have seemed rather to complicate than clarify existing problems. In his Croonian Lectures—published in this and last week's *Journal*—Professor N. Hamilton Fairley has fitted the new pieces of knowledge together and enabled them to be seen in perspective. It seems that *Plasmodium vivax* and *P. malariae* exist in man in five distinct forms—the sporozoite, the pre-erythrocytic form in the liver, the schizont in the red blood corpuscle, the exo-erythrocytic form in the liver, and the gametocytes in the red cells. *P. falciparum* apparently does not develop the exo-erythrocytic form, but is otherwise similar. The sporozoite is merely a transitional stage inoculated by the mosquito, and it quickly changes into the pre-erythrocytic form, which then multiplies in the body. The schizont, which incidentally produces the fever, seems to be a rather unnecessary phase in the protozoon's life history, except that gametocytes perhaps branch off from it to constitute the form infective to mosquitoes. The exo-erythrocytic stage is not essential for the protozoon's survival, but provides a long-living resistant reservoir from which new broods of schizonts arise; these cause clinical relapses and are the source, directly or indirectly, of fresh gametocytes which may ensure the organism's ultimate survival.

Each of these forms reacts differently to drugs, and it is now hardly surprising that the old quest to find a drug which would eliminate the schizont and the fever it caused had little success in so far as the radical extermination of the parasite was concerned. Perhaps all forms are susceptible in some degree to the action of the known antimalarial drugs. Within the limits of tolerated doses quinine, mepacrine, and chloroquine are effective against schizonts only. In consequence they offer no prospect of radical cure of *P. vivax* infections, which may continue in the exo-erythrocytic form untouched by the drug. They are not true causal prophylactics, though when properly administered mepacrine and chloroquine may destroy the schizont so rapidly that clinical signs are suppressed; in consequence they appear to act as true prophylactics against *P. falciparum* infections and are good suppressants of the others. Proguanil has a wider range, acting on the pre-erythrocytic form of *P. falciparum* malaria as well as on the schizonts and gametocytes of all species. It is therefore a true causal prophylactic of *P. falciparum* malaria and a suppressant of *P. vivax* infections; it brings about a clinical but not a radical cure of *P. vivax* infections, and renders gametocytes non-infective to mosquitoes. The range of the 8-amino-quinolines—pamaquin, pentaquine, and iso-pentaquine—is still wider, for they have an observable effect on the pre-erythrocytic, schizogony, exo-erythrocytic, and gametocyte stages. This group is therefore the only one from which there is a prospect of obtaining an efficient antimalarial drug for the clinical cure, radical cure, and prophylaxis of all forms of malaria. Unfortunately the toxicity of these drugs makes them useless for the control of schizogony and its clinical effects or for prophylaxis, and for other purposes they should be administered under strict medical control. Efforts in the U.S.A. to discover less toxic members of this group have met with some success, for recent reports indicate that iso-pentaquine has a maximum tolerated dose about four times that of the original pamaquin, while weight for weight it is apparently slightly more effective. It is, however, still too toxic to be of any use as a prophylactic or schizonticide, or to be taken except under medical supervision. For the time being, then, until some drug is discovered with the range of action of the 8-amino-quinolines but without their toxicity, a variety of drugs must be prescribed, according to the purpose of medication and the species of parasite concerned.

Professor Fairley's account of the life history of the parasite is satisfying in that it explains all the known facts, and most of it has been objectively proved, but a great field lies open for further work. The pre-erythrocytic cycle of *P. falciparum* malaria is still hypothetical; happenings in the "premune" state are obscure; the relationship between "premunity" and re-action to treatment requires further investigation; there is no effective prophylactic against *P. vivax* malaria; the risk of parasites acquiring tolerance to proguanil and perhaps other drugs cannot be ignored; some of the available drugs are too toxic for common use; and the variety of drugs needed for the treatment of one disease is greater than desirable. In the past work has been slow because it has largely depended on human volunteers, often intentionally inoculated, in whom the course of events had to be laboriously studied for several months. The recent use of parasites of birds and monkeys has greatly eased the preliminary work, but this is not entirely satisfactory, because the relationship

[1] *British Medical Journal*, 1949, 2, 222.

between avian and human parasites is insufficiently close, and the monkey is an expensive and difficult animal for large experiments. More rapid progress could be made if the human parasites could be cultured in ordinary laboratory animals or if a closely related parasite could be found in one of them. The discovery of a new *Plasmodium* (*P. berghei*) in Congo tree rats holds out hope that the second of these conditions may be fulfilled. It is not yet certain that it will be, because mosquito transmission, not mere blood inoculation, must be maintained, and the anopheline vector, probably *Anopheles dureni*, has not been finally confirmed or established by culture in Europe or America. If the difficulties in using this parasite could be overcome and large stocks of the rats infected by mosquito transmission maintained, it should be possible to screen drugs in a much more realistic manner than before by tracing their immediate effects on each form of parasite by post-mortem examination. Chemotherapeutic research would thus be greatly accelerated, though the need for final confirmation on man would remain.

These advances in the treatment of malaria come at a time when its prevention is being undertaken on a rapidly increasing scale. Total extinction, eliminating the need for treatment, is still beyond the vision of even the most enthusiastic. Progress in mosquito control—a subject discussed in a recent leading article[1]—has, however, advanced to the stage when many doubt the place of mass therapy or drug prophylaxis in the protection of the civilian population except during epidemics, believing that the funds and administration needed for them could more effectively be used in mosquito control. The field of treatment is, therefore, becoming narrower in comparison with past years, but this is all to the good if it means that blunderbuss therapy gives way to the practice of scientific medicine.

TUBERCULOSIS IN ENGLAND AND SCOTLAND

The death rate from respiratory tuberculosis in England and Wales is now only one-quarter of the rate of one hundred years ago. At that time the death rate for females was higher than that for males, but because it fell more rapidly it is now lower than the male rate. In 1851–60 the standardized death rate for males was 2,694 and for females 2,854 per million; in 1921–30 the figures were 868 for males and 677 for females. The death rate for both sexes continued to decline until 1939, when the war interrupted the trend and the rate began to increase. The peak was reached in 1941, but after remaining at a high level for two years the rate fell, and in 1946 and 1947 it was below the pre-war figure. The death rate from non-pulmonary tuberculosis has followed a similar but not parallel trend. The speed of decline was slower at first, but since the beginning of the century the fall has been faster for non-pulmonary than for pulmonary tuberculosis. Again there was a rise during the early war years, but since then the rate has declined more rapidly than that for respiratory tuberculosis. The comparative mortality index for non-pulmonary tuberculosis in 1947 was only three-quarters of the 1938 value, while the index for respiratory tuberculosis was slightly over nine-tenths of the 1938 value.

Judged from the trend of the death rates the present position appears to be satisfactory, and a continued fall in mortality might safely be expected. But a doubt is cast on this prediction by the notification figures. The number of new cases diagnosed rose from 40,742 in 1938 to 47,186 in 1947. How far this signifies a true increase in the incidence of tuberculosis is problematical. It may be due, in part at least, to more strenuous efforts to diagnose and control the disease: the large decrease in notifications, almost 2,000, recorded in 1940 indicates that notification is related to the facilities for diagnosis and treatment. The greater number of notifications may also be partly due to mass radiography. Many minimal lesions have been found that would otherwise have escaped detection. It is impossible at present to estimate in what proportion of these cases the infection becomes clinically active during observation, but it should be possible to answer this question during the next few years. The higher number of notifications probably does not signify an actual increase in incidence. But there has been no falling off of the number of deaths from tuberculosis of persons not notified before death. In fact there has been in recent years a slight increase; the numbers not notified before death were 3,468, 3,603, 3,580, and 3,682 for the four years 1944–7. In 1947 13% of the persons dying from respiratory tuberculosis were not notified during life; in 1938 the figure was 9%.

The proportion of tuberculous patients being treated in institutions in 1947 was 2% more than in 1946; but the demand for hospital beds had not been met, and the delay in admission had increased. In the first quarter of 1947 there were 32,586 beds provided, of which 4,618 were temporarily not in use—mainly because of lack of staff. The situation improved during the year, and in the last quarter the percentage of beds available but out of use dropped from 14.2 to 11.5. This was, however, offset by the rapid increase in the numbers on the waiting-list. In the first quarter of 1947 6,882 persons were awaiting institutional treatment, and by the last quarter the number had gone up to 8,269. Adequate staffing of all available beds would reduce the number on the waiting-list by almost one-half. The rise in the numbers awaiting admission may be due partly to the fact that modern treatment necessitates a longer stay in hospital, partly to a real

increase in incidence, or partly because patients are placed on the waiting-list in an earlier stage of the disease, with the result that there is a smaller loss through deaths before admission. Whatever the cause, or combination of causes, there are not enough beds.

In Scotland the trend of the death rate from tuberculosis has been similar to that of England and Wales, though the figures have been consistently higher. The rate did not start to decline so early in Scotland, but from 1866 it fell until 1939, when a rise occurred. Contrary to the post-war experience of England and Wales the tuberculosis death rate in Scotland failed to decline, the death rate from respiratory tuberculosis being 64 per 100,000 in 1946, 66 in 1947, and 66 in 1948—a reversion to the level of 20 years earlier. A few weeks ago in this *Journal* Mr. Walter Elliot[1] described the failure of the rate in Scotland to follow the same trend as the English rate as "a fascinating problem of public health to which no solution has yet been found." In a letter published in last week's *Journal* (p. 869) Dr. Ian Sutherland, of the Institute of Social Medicine at Oxford, compared the mortality from the disease in England and Wales and in Scotland by sex and age: in his opinion the statistical evidence indicates that "the mortality from pulmonary tuberculosis among young adults in Scotland compares very unfavourably with that in England and Wales, and is relatively much worse now than it was early in the war," and also that "the increase which has occurred since the war in the death rate from the disease among Scottish women aged 15 to 34 is a matter meriting the fullest investigation."

Notifications of respiratory tuberculosis in Scotland were diminishing in the pre-war years, but recently they have risen steadily each year, from 4,637 in 1939 to 8,010 in 1948, and are now at the same level as in 1921. The rate of increase exceeds that recorded in England and Wales. Despite the rapid rise in the number of notifications a large proportion of tuberculous persons escape notification during life; 530 (15%) of the 3,472 persons who died from respiratory tuberculosis in 1947 were notified only at or after death.

It is even more difficult to obtain a vacancy in a sanatorium in Scotland than it is in England. The number of available beds rose from 4,263 at the end of 1946 to 4,707 at the end of 1947, while those empty through lack of staff decreased from 742 to 572, but the waiting-list increased from 1,889 to 2,572 during these years—if there had been enough staff this would have been reduced by one-fifth. The number of staffed institutional beds available for the treatment of respiratory tuberculosis in Scotland is only about two-thirds of the estimated minimum requirement. While Scotland has its special difficulties it is plain that the control of tuberculosis presents fundamentally the same problems in England, Wales, and Scotland. As Sir Andrew Davidson, Chief Medical Officer of the Department of Health for Scotland, recently remarked,[2] "The present need is for full and adequate co-operation between the health officers and the hospital services." New methods of prevention and treatment are being rapidly developed, and it is essential that all doctors engaged in the task of eradicating tuberculosis should work closely together so that useful knowledge is disseminated with the shortest delay.

CHEMOTHERAPEUTIC TREATMENT OF TYPHOID

The chemotherapeutic treatment of typhoid may be said to have begun in 1887 with the observations of Chamberland[1] that the vapours of certain essential oils—sweet marjoram, camphor, sandalwood, and cloves—had an inhibitory action on the growth of typhoid bacilli. The earlier sulphonamides appeared to give some protection to mice against multiple lethal doses of *S. typhi* and *S. paratyphi B*,[2] but Britton[3] was unable to detect any bacteriostatic or bactericidal action *in vitro* on the growth of these organisms by sulphanilamide or allied drugs, and in human infections results were contradictory. With the discovery of the action of sulphaguanidine and sulphasuxidine on the organisms of bacillary dysentery hopes were raised that a cure for typhoid also might be in sight, but though abdominal discomfort was sometimes reduced the fever and general course of the infection were uninfluenced. With penicillin the same story was repeated: occasionally good results were obtained, but more often they were similar to those reported by Riser and his colleagues,[4] who found that in one chronic typhoid carrier bacteriological tests became negative after a total dose of 2,200,000 units, and in a second they became negative after 2,650,000 units but relapsed one week after the drug had been stopped. Streptomycin *in vitro* appears to inhibit the growth of *S. typhi* in concentrations of from 1 to 16 units per ml., but in man the results are unimpressive. Of 11 patients with *S. typhi* or *S. paratyphi A* infections, including three carriers, treated by Pulaski and Amspacher,[5] nine recovered and only two died, but in the six cases where *S. typhi* was the causative organism there was no real evidence that streptomycin had shortened the course of the infection. It was concluded that parenteral streptomycin alone was useless, but that possibly combined oral and systemic penicillin might be of value.

Very much more encouraging results have been obtained with chloramphenicol ("chloromycetin"), which was first used in Malaya by Woodward and his

colleagues[6] almost as a by-product of their investigations on scrub typhus. We have already drawn attention to these studies[7]: 10 patients were successfully treated, though two relapsed after afebrile periods of 10 and 16 days and one had a haemorrhage. The average total dose was 19.1 g. per patient, given over an average period of 8.1 days. Both the patients who relapsed were cured by further chloramphenicol. These preliminary results have been amply confirmed. Murgatroyd[8] reported one dramatic recovery in this *Journal*: a total dosage of 22.75 g. was given. Bradley[9] gave preliminary findings relating to the use of the drug during an epidemic in Berkshire in which an attempt was made to obtain an unbiased result by treating alternate cases: the change in the constitutional symptoms was remarkable, though three of nine patients relapsed. Among all those treated with chloramphenicol in this outbreak four only relapsed, and these responded to further doses of the antibiotic. Douglas[10] treated two cases, in one of which administration of chloramphenicol was begun on the third day of illness. The dose was 4 g. in the first hour, 0.25 g. two-hourly until the patients were afebrile, and then 0.25 g. four-hourly until a total of 20 g. had been given. Four days after beginning treatment the temperatures were normal, but though blood cultures on the second, third, and fourth days were negative *S. typhi* was present in the stools until the sixth day. There were no relapses. In this issue of the *Journal* Dr. W. Lomax describes the successful treatment of a severe infection which the patient contracted in Egypt and which developed on the voyage to England. From the U.S.A. Foster and Condon[11] record complete remission of the temperature in 96 hours in a patient who had shown no change after streptomycin therapy for four days. In Syria Kiledjian[12] successfully treated three patients infected with *S. typhi* and one with *S. paratyphi B*, and from Transjordan Tutunji[13] reported good results in two girls with *S. typhi* infections. No relapses were recorded. Shah[14] and Vakil[15] in India describe the use of chloramphenicol in series of 33 and 14 cases, though since blood cultures were not always performed it is uncertain how many of these patients were actually suffering from typhoid. Elsewhere in this issue Drs. J. C. Patel, D. D. Banker, and C. J. Modi, of Bombay, describe a series of six cases in which the blood cultures were all positive. As noted by other workers, the constitutional symptoms improved before the fall in temperature, which occurred very frequently in two stages—an initial reduction being followed by a rise and then by a slower subsidence. One of the six cases relapsed. In Egypt El Ramli[16] found that of 17 patients treated with chloramphenicol nine relapsed, whereas among 122 previous cases treated with other drugs only 16 had relapsed. In a series of 45 cases treated in Port Said and as yet unpublished there were only two relapses. The largest series of cases so far recorded is that by Musotto,[17] who describes a water-borne outbreak of typhoid at Pozzallo, near Ragusa, in which some 500 cases occurred. Unfortunately in his preliminary account he gives no precise figures, but all severe cases were treated with chloramphenicol and excellent results were obtained. The initial dose was 50 to 60 mg. per kg. of body weight in the first hour, capsules being given every 10 minutes, followed by a maintenance dose of 0.25 g. in adults and 0.12 g. in children every two to three hours. When the temperature had fallen to normal the same maintenance dose was continued four-hourly for at least five days. With this regime there were few relapses, and these promptly responded to further chloramphenicol. One patient who had an intestinal perforation recovered.

Comparatively few cases of paratyphoid infection have so far been treated. In Musotto's series there were a number of paratyphoid A infections which apparently responded satisfactorily. Montuschi[18] treated one case of paratyphoid B which reacted somewhat slowly: the temperature did not fall till the fourth day of treatment after 0.5 g. had been given three-hourly for 24 hours. Christie[19] briefly refers to eight cases of paratyphoid of unspecified type. One child died after six days' treatment with chloramphenicol; in most of the seven other cases the temperature became normal after four to five days, though one patient was afebrile in 48 hours. This result is no better than that in children treated on conservative lines, though it is mentioned that in another series of 10 children to whom no antibiotic was given pyrexia persisted for from nine to 15 days. It is thus possible that paratyphoid infections react less

readily to chloramphenicol than does typhoid. Further investigations are obviously necessary.

From published reports it appears that chloramphenicol does not readily induce drug-fastness, a point greatly in its favour. It is very nearly free from toxic effects, though Musotto and Patel and his colleagues refer to eczematous skin rashes. Ramli mentions anorexia, stomatitis, glossitis, mental apathy, and skin rashes. The most frequent complaint is of slight nausea, but it should be emphasized that reactions are both rare and mild. The greatest drawback to chloramphenicol is that in the doses used it is often bacteriostatic rather than bactericidal. This is borne out by Rumball and Moore,[20] who gave a chronic typhoid carrier, a boy 9 years of age, 10.5 g. in seven days without any effect on the presence of *S. typhi* in the stools: a further course of 5.25 g. in seven days caused the stools to become negative, but two days after treatment had ceased the organisms were again being excreted.

Since chloramphenicol in the doses so far used cannot be guaranteed to destroy all typhoid organisms in the body, three further methods of treatment have been explored. Other recently discovered antibiotics have been tested: aureomycin was given by Musotto to six patients, but the diarrhoea and vomiting were such that it had to be stopped. In India, Patel and his colleagues[21] also found aureomycin of no value. Polymyxin has been tried in five cases and found to be useless.[19] The administration of chloramphenicol for a longer period has been recommended. Smadel and his colleagues,[22] who incidentally find that synthetic chloramphenicol is quite as effective as the natural form, now recommend that the antibiotic should be given for not less than nine and not more than 14 days. Thus of 13 patients treated for eight days or less (average 6.9 days) seven relapsed; of 19 patients treated for nine to 14 days (average 11.2) none relapsed; and of 12 patients treated for 14 to 23 days (average 18) none relapsed. The total dose of chloramphenicol in the three groups averaged 13.5, 13.7, and 20.8 g. respectively. The dosage now recommended is 4 g. (16 capsules) in the first hour, followed by 1.5 g. (six capsules) twice daily till the patient becomes afebrile; then 0.75 g. (three capsules) twice daily for one week. The administration of the drug twice daily is less disconcerting for the patient and makes for easier nursing.

The third method which is being investigated is that of combined therapy. A synergistic action between penicillin and sulphonamides on *S. typhi* in mice was reported by Bigger[23] and has been confirmed by Knapp[24] and by El Borolossy and Buttle.[25] Advantage has been taken of this phenomenon in the treatment of typhoid in man by McSweeney,[26] but while some observers have obtained good results[27 28 29] others have entirely failed to demonstrate any synergistic effects.[19 30 31 32] The explanation for this divergence is that various strains of typhoid bacilli vary greatly in their sensitivity to penicillin. A similar synergistic action was found in mice by El Borolossy and Buttle with sulphadiazine and chloramphenicol. In human cases a combination of sulphathiazole and chloramphenicol might possibly be preferable to sulphadiazine and chloramphenicol, though it should be noted that Schweinburg and Yetwin[33] found *in vitro* that sulphamezathine is more bactericidal and bacteriostatic than sulphadiazine against *S. typhi*. There is thus a possibility that synergistic treatment of human typhoid infections with chloramphenicol and a sulphonamide may overcome the tendency to relapse characteristic of insufficient dosage with chloramphenicol by producing a rapid bactericidal effect.

THE ARTIFICIAL KIDNEY

In spite of much effort and ingenuity it is fair to say that the artificial kidney is still only an ideal and not an accomplished fact. In the opening pages of this issue Drs. Gordon Murray and E. Delorme and Mr. N. Thomas describe one form of "artificial kidney"; similar devices have been used by Kolff[1] and Alwall.[2] In all of them heparinized blood is led through a long cellophane tube immersed in a bath of fluid in which salts of sodium, potassium, calcium, and magnesium have been dissolved to simulate the electrolyte pattern of normal plasma. The cellophane membrane allows the passage of urea, electrolytes, and water, but not of protein or of red cells; as the blood flows along urea diffuses out into the bath fluid, while electrolytes diffuse outwards or inwards depending on whether their concentration in the actual plasma is greater or less than that in the "ideal plasma ultrafiltrate" of the bath fluid. In this way the blood leaves the apparatus having lost some of its diffusible non-protein nitrogen and having had its electrolyte composition restored to a somewhat arbitrary "normality."

The principle is simple enough, but its translation into practice brings difficulties to the doctor and real hazards to the patient. If the cellophane tube is made long enough to allow the dialysing process to be anything like complete, then the arterial blood pressure becomes an inadequate driving force and some sort of pump has to be introduced into the apparatus. Kolff uses a helical pump, having found a satisfactory way of joining the stationary tube in a vein to the tube wound round a rotating drum. Murray and his colleagues incorporate a syringe pump with rubber inlet and outlet valves, and claim that the use of large amounts

of heparin will prevent clotting on the valve flaps. Again, if the tube is long its internal volume may be appreciable in relation to the volume of blood which can be safely withdrawn, however temporarily, from the patient. The authors overcome this difficulty by "priming" their apparatus with suitable blood. Besides such difficulties, which are inherent in the apparatus, there are the further dangers of haemorrhage in a patient whose blood has to be made incoagulable by heparin throughout the period of dialysis. Also the anuric patient cannot protect himself against dehydration or water overload, and these may easily arise if the composition of the bath fluid is unsuitable.

The dangers of the artificial kidney are admitted by its makers and users, but they argue that acute renal failure is so serious a condition that desperate measures may be justified. This contention is based on the assumption that acute renal failure carries a very grave prognosis, and figures can be found which support this view. Several critical surveys have lately appeared, however, which show that the high mortality of anuria is largely attributable to faulty treatment, and that conservative treatment gives good results provided that excessive amounts of fluid are not given. Muirhead and his colleagues[3] found that renal function recovered spontaneously in most patients with anuria "provided they are not overloaded with salt and water in the vain attempt to stimulate urine production." Similar results were reported by Stock,[4] who found that the mortality in 22 patients with anuria was only 50% and that in the majority of the 11 fatal cases fluid overload was a more important feature than nitrogen or other retention. Even more convincing is the experience of Bull and his colleagues[5] at the London Postgraduate School, who have advisedly given up the use of the artificial kidney in favour of a high-calorie low-protein diet and a controlled fluid intake of a litre per day. They have had good results with this regime, and it can be safely carried out by those who lack the technical knowledge and fortitude to maintain a patient on the artificial kidney.

It seems clear that until artificial kidneys become safer they have no place in the treatment of acute renal failure. To say this is not to suggest that the work done in this field has been wasted or that it should not continue. Already the excretory functions of the kidney can be artificially performed for a short time, not only by the various forms of artificial kidney but also by such expedients as peritoneal irrigation[6] or intestinal intubation.[7] All these methods require the use of large volumes of irrigating fluid, since the excreting surfaces have no power to concentrate metabolites; they can therefore be used only in special clinics, where a close watch can be kept on the electrolyte composition of the plasma. So far no artificial method has been found for performing the homeostatic, as opposed to the excretory, functions of the kidney. This is a serious matter, for while it is logical to suppose that continued failure of renal excretion would cause death, the observed facts indicate that in acute anuria immediate danger arises from the patient's lack of any effective defence against overloading with water and salt. Bull and his colleagues[5] believe that water intoxication is a real risk in such patients. When patients with anuria have already been maltreated by large infusions, a policy of deliberate and controlled dehydration may be indicated, and intestinal perfusion with 5% lactose, as used by Brun in Copenhagen, may be a suitable way of doing this.

ASTHMA

Reports on the value of antihistamine drugs in asthma have, on the whole, been disappointing.[1-5] Their failure, however, is only relative in comparison with the great relief of symptoms which these drugs give in some cases of acute urticaria and hay-fever, in the treatment of which they have a permanent place. Most observers claim that in the symptomatic treatment of asthma the antihistamine drugs can be of value.[2-6] Elsewhere in this issue Dr. H. Herxheimer substantiates these claims and gives particulars of the partial relief of artificially induced and naturally occurring attacks of asthma afforded by various antihistamine drugs. In the routine treatment of asthma they are especially useful in preventing nocturnal attacks, and in this respect they seem to be superior to ephedrine or adrenaline analogues both because of their sedative side-effect and because some at least continue to exert their action for a much longer period of time. Even so, their value in asthma is limited. In some of Herxheimer's cases the antihistamine drugs were quite ineffective, severe attacks of asthma not being controlled even after large doses. Moreover, though the vital capacity was often notably increased, in no case was it restored to the maximal, and therefore presumably normal, figure for the patient. It may be that with newer, more potent preparations, less apt to cause unpleasant side-effects, better results will be obtained. At the moment the place of antihistamine drugs in the treatment of asthma must remain *sub judice*.

Some observers have pointed out that these drugs are valueless in the presence of bronchial infection or nasal abnormality.[2 5] It is indeed not surprising that the response to treatment varies considerably. On the evidence available few would maintain that asthma is invariably caused by the action of histamine on the bronchioles, or even agree with Drs. E. O. and G. E. O. Williams, whose paper on the natural history of asthma appears in this issue at page 897, that it is always due to bronchiolar spasm: oedema of the submucosa probably plays an almost equally important part. These authors emphasize the variation in aetiological and aggravating factors in asthma, the absence of any clear-cut relationship between them, and, by implication, the present ignorance of the essential pathogenesis. Most of the factors commonly regarded as of aetiological importance act merely as detonators which explode the hidden charge, thus converting the latent into the overt asthmatic.

Williams and Williams bring evidence to show that the onset of asthma and of subsequent attacks is in some cases definitely related to the disturbances associated with

pregnancy and menstruation. Such observations are of course not new, but evidence is accumulating that sensitization to endocrine products may cause asthma.[7 8] If this is so, and more information must be collected before such a view can be accepted, the whole field of autosensitization as a cause of asthma must be re-explored. In summing-up the evidence, it must be remembered that pregnancy often exerts a beneficial effect in chronic asthma, and that psychological disturbances which may be of aetiological importance occur commonly during pregnancy and menstruation. Another significant observation is that eleven out of sixty-four patients followed up for a period of from 7 to 12 years had died, six as a result of their asthma. Flensborg recorded a mortality of 5% in a group of children seen between 1926 and 1939.[9] Asthma not only cripples, it can also be a killing disease.

INSULIN REQUIREMENTS

Newspaper reports of scientific work are seldom sufficiently detailed or accurate to make it possible to express any opinion on the merits or conclusions of the work described. In the *New York Times*[1] there recently appeared an article by William L. Laurence in which are summarized studies carried out on 4,000 diabetic patients over a period of 14 years by a group of chemists and physicians of the Jewish Hospital of St. Louis, headed by Dr. Michael Somogyi. These workers are said to have come to the remarkable conclusion that provided proper attention is paid in treatment to dietary control 99% of adult diabetics do not require insulin. The essence of such control appears to be the reduction of weight to the ideal level and the dietary restriction of fats—protein and carbohydrate apparently being allowed in liberal amounts. The scientific arguments, as reported, need not be considered at this stage, and in the absence of detailed case reports no conclusions can be drawn about the validity of the remarkable claim made by Dr. Somogyi and his co-workers. The statement that less than 1% of adult diabetics require insulin is, however, so contrary to the experience of workers throughout the world, including the U.S.A., that it should not be accepted without very careful study of the evidence on which it is based. Until such evidence is available both diabetics and those who treat them will be wise to adhere to the generally accepted principles of treatment which are based on considerably more than 14 years of intensive study and research on many thousands of cases of diabetes. If Dr. Somogyi and his colleagues have only discovered that there is a large group of obese diabetics in whom a reduction in weight is the most effective form of treatment and in whom insulin is not only unnecessary but usually contraindicated, then nothing new has been added to our knowledge of the treatment of diabetes. If, on the other hand, as the article in the *New York Times* suggests, the conclusions apply also to the young adult with severe diabetes, the whole conception of insulin therapy in diabetes will have to be readjusted and the importance of Banting and Best's great discovery reassessed; it is unlikely that time will prove this to be necessary.

WMA

An account of the proceedings of the General Assembly of the World Medical Association is published in this week's *Supplement*. From this it will be seen that the interest of this new body extends over a wide field of medicine—medical ethics, international medical congresses, hospitals, pharmacopoeias, postgraduate education, and social security. Perhaps the most interesting debate was on the last item based on the report of a committee of which Dr. Charles Hill was chairman. This report presented a factual summary of the conditions now existing in 24 countries. Dr. H. Guy Dain summarized for the foreign visitors what he called the teething troubles of the National Health Service. Our colleagues from other countries were restrained in their criticism of the system adopted in Britain, but those who spoke did not consider that the British N.H.S. was the final solution to the problem of providing medical care. Dr. Paul Cibrie, for example, considered that the capitation method of paying the doctor put him at the mercy of his patient. Dr. W. Magner said that while the Canadian Medical Association approved the principle of contributory health insurance it would oppose any Act modelled on the British Act. For the U.S.A. Dr. W. Cline told how in his country the medical profession were developing and enlarging the voluntary insurance system, and considered that the care of the indigent was the responsibility of the local community. Dr. S. C. Sen gave some idea of the tremendous problems facing India when he observed that for a population of 350 million there were at present only about 50,000 qualified doctors.

The position of the general practitioner in medicine is evidently causing concern abroad as well as at home. The view was expressed that in these days there was a tendency to look down upon the general practitioner, and Dr. Dag Knutson observed that if the general practitioner accepted an economically lower status than the specialist he would continue to be looked down upon. There was some discussion on a proposition in one of the committee reports about the work of general practitioners in hospitals, and the Assembly approved of the suggestion that general practitioners should be integrated into the Hospital Service. Dr. Fishbein pointed out that the tendency of medical progress was to give the general practitioner the opportunity of treating cases that formerly went to the specialist. The development of medical services is closely linked with the work and status of the general practitioner, and it seems likely that these two problems will come to the fore in the discussions held by the WMA during the coming year.

It has been announced in Oslo that the Nobel Peace Prize for 1949 has been awarded to Lord Boyd-Orr, M.D., F.R.S., Chancellor of Glasgow University, and formerly Director-General of the United Nations Food and Agriculture Organization. Sir John Boyd-Orr, as he then was, was created a Baron at the beginning of this year. In Stockholm last month he was re-elected President of the World Movement for a World Federal Government. The Nobel Peace Prize is said to amount to £7,815 at the present rate of exchange.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

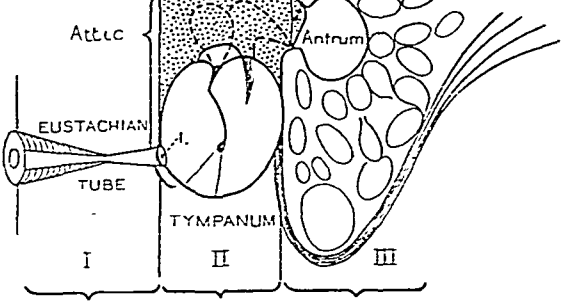
THE ACUTE EAR

BY

W. M. MOLLISON, F.R.C.S.

Consulting Surgeon, Ear and Throat Department, Guy's Hospital

The cardinal symptoms of ear disease are earache, deafness, vertigo, and tinnitus. Any of these symptoms, if of acute onset or if severe, might be called an "acute ear." This article will deal only with acutely painful affections of the external and middle ear. The pain is, in the majority of cases, inflammatory, but in a small minority no local lesion is to be found in the meatus or tympanic membrane.



To decide whether the site of pain lies in the external or middle ear it is essential to examine the ear carefully. The electric auriscope affords the easiest view, especially if the patient is a child or is in bed. The skin of the meatus is normally pale pink, and the presence of the speculum should cause no discomfort. The tympanic membrane can be seen at a distance of about one inch (2.5 cm.) from the concha. Since the ceruminous glands and hair follicles occupy only the outer two-thirds of the meatus, infections—e.g., boils—occur only in this area.

Acute Infections of the External Ear

The Pinna.—The pinna is subject to the same infections as other parts of the skin and does not come within the compass of this article.

The External Auditory Meatus.—Furunculosis, or boils in the glands or hair follicles of the outer two-thirds of the meatus, is an extremely painful condition. At an early stage the boil may be too small to produce any swelling and can be diagnosed only by the presence of an area of red skin and the discovery of a tender spot by a probe. Later, an obvious tender swelling or swellings simplify the diagnosis.

The lymphatics of the meatus drain to glands (1) in front of the tragus, (2) behind on the surface of the mastoid process, and (3) below the tip of the process. Tenderness in any of these positions is an aid to diagnosis. Lymphangitis may occur as a complication. The swelling to which it gives rise is over the mastoid process and is often sufficient to push the pinna forward and downwards. It pits on pressure and may raise a suspicion of acute mastoiditis with subperiosteal abscess. The type of tenderness differentiates between the swellings—that of lymphangitis is superficial, and if pressure is maintained the bone can be reached without causing any increase in pain; in the case of mastoiditis, on the other hand, the harder the pressure the worse the pain.

1. Opening of tube into tympanum. 2. Aditus—opening from attic into the antrum. 3. Plate of bone forming the roof of attic in front and of the antrum behind; it is also the floor of the middle cranial fossa. 4. Dura mater.

No loss of hearing occurs in furunculosis unless the boils are extensive enough to block the meatus; even then a narrow speculum insinuated between the boils will restore hearing to normal.

Treatment of Furunculosis

The meatus, including that part deep to the boil, must be kept clean and dry. Every otologist has favourite drugs for this purpose, either in the form of drops or for application on gauze wicks. Well-tried prescriptions are:

Glycerin of phenol and glycerin, equal parts.
Saturated solution of magnesium sulphate, with or without glycerin.
Ichthyol in glycerin (10%).
Gentian violet in spirit (2%).
Silver nitrate (10%).
Aluminium acetate (8%).

Penicillin drops should not be used.

Incision should only be employed when a furuncle shows pus at its apex, though rupture of the boil may be hastened by the application of a minute drop of pure carbolic acid. The application of warmth is comforting, and an electrically heated pad is satisfactory for the purpose.

Although a course of sulphonamide may effect a dramatic cure, the fact that so many different drugs have been advocated is an index of the unsatisfactory results of treatment of this most painful affection.

Acute Infections of the Middle Ear

Any acute infection of the upper respiratory tract involves the nasopharynx and may spread to the Eustachian tube and so to the middle ear.

Anatomy.—The middle-ear tract extends from the nasopharyngeal end of the Eustachian tube, through the tympanum or middle ear, and thence through the aditus to the mastoid antrum to the air cells in the mastoid process. The tract may be conveniently divided into three parts: (1) The Eustachian tube, (2) the middle ear or tympanic cavity, and (3) the mastoid antrum and mastoid cells (see Figure). Inflammation may be mainly confined to part 1, or to parts 1 and 2, causing acute otitis media. Inflammation can spread from here through the aditus to the mastoid antrum. It is probable that some inflammation develops in the antrum in most cases of acute otitis media, and in suppurative cases the mastoid cells become involved to produce acute mastoiditis. In the case of severe haemolytic streptococcal or pneumococcal infections the whole tract may be rapidly involved.

desired to maintain a column of heparin unmixed with blood in the tubing and attachment.

Serial estimation of clotting time has shown that the polythene does not impair the anticoagulant effect of heparin. The apparatus has been used mainly for the initial administration of heparin to patients suffering from intravascular thrombosis for the period of two to four days before dicoumarol, simultaneously administered, has exerted its effect. It has also been employed effectively for much longer periods in patients in whom there existed a specific contraindication to dicoumarol therapy.

It is essential that the strictest sterile precautions are observed in the preparation and setting up of the apparatus. The tubing is most conveniently inserted at the antecubital fossa, where veins are most easily found (see Fig. 2). The patient is still able to flex the elbow and retains reasonable use of the arm. It is felt that the apparatus has considerable advantages over an indwelling intravenous needle, such as that described by Olovson (*Lancet*, 1948, 2, 495), in that it is more comfortable for the patient, allows free movement of the limb, and is not liable to require changing, since the polythene stimulates no foreign-body reaction. Furthermore, the special attachment is more easily cleaned and sterilized than the cumbersome indwelling needles that have been described. If polythene is not available the attachment can, of course, be inserted into any Record-fitting intravenous needle to serve as a simple indwelling apparatus.

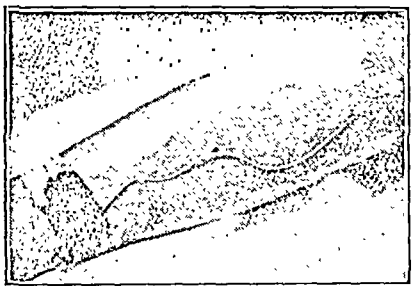


Fig. 2.—Intravenous polythene tubing in use. The skin has been painted with iodine to demonstrate the cannula more clearly. For the same reason the latter has been left longer than is necessary.

I wish to record my gratitude to Dr. A. Fergus Hewat, physician, Royal Infirmary, Edinburgh, for his kindness in permitting me to study the cases under his care.

Reports of Societies

PROGRESS IN OPHTHALMOLOGY

In his presidential address to the Section of Ophthalmology of the Royal Society of Medicine on October 13 Mr. Montague Hine said that this was a suitable occasion on which to stress the continued progress of ophthalmology. A similar review in a presidential address to the Section was given in 1926 by Mr. Ernest Clarke, who carried his story back to 1881 when he started ophthalmological practice. Mr. Hine took up the story from the point where Mr. Clarke left off. During these last 23 years, he said, treatment in many directions had improved, new operations had appeared or old ones had been perfected, and recently discovered remedies were being used with remarkable results. In addition much work had been done on the pathology and biochemistry of the eye, the full harvest of which had not yet been reaped.

The most spectacular advance in surgical treatment had been for detachment of the retina. The first Gonin type of operation at Moorfields was carried out in 1930. During the next year or two the means of obtaining a less localized reaction in the choroid and retina was sought for, and after some trial and error very weak diathermic currents were found to be most suitable, and these replaced the cautery in 1933. Since that time it could fairly be said that among unselected cases some 50% had been successfully treated, though a considerably higher figure—up to 75%—could be obtained if the material was of better quality and the operator more experienced. This was a very different story from the pre-Gonin days, when less than 1% of all detachments were successfully treated. It seemed almost a miracle that in the course of a few years after 1929 the treatment of detachment, from being one of the most hopeless procedures in ophthalmology, became one of the most hopeful. In 1926 in the Moorfields group the operations for detached retina by cautery puncture numbered only 20; in 1947 with the use of diathermy there were over 500 such operations.

Mr. Hine then touched on the treatment of squint, comparing the figures for 1926 and 1947. There was no doubt, he said, that orthoptic departments were of great assistance to ophthalmic surgeons and had influenced their views on operative measures. There were now 800 squint cases awaiting admission into the hospitals of the Moorfields group. He was rather surprised a few weeks ago to encounter a resident officer at one of the eye hospitals who confessed that he had never seen an excision of the lacrimal sac. In 1926, 96 cases of excision of the sac were recorded at Moorfields and 23 at the Royal Westminster Hospital; in 1947 the numbers were respectively 44 and 9, but in the latter year dacryocystorhinostomy—not a difficult operation—was carried out on 46 cases at the former hospital and 22 at the latter. The first record of this operation in the Moorfields reports was in 1932, but not until 1944 did it become the method of election among ophthalmic surgeons in this country and in America.

The development of corneal grafting dated from the experimental work of Tudor Thomas in 1930–4, and the first successful graft of a human eye in Great Britain was in 1933. Now this operation was undertaken by many ophthalmic surgeons. In 1947 five cases were operated on at Moorfields and four at the Royal Westminster.

Turning to contact lenses, he said that in 1926 it was only rarely that such a lens was ordered. Some few thousand contact lenses were now being made in Great Britain. The use of transparent plastic material for some optical appliances was a development of the last twenty years. Finally he made a brief mention of new drugs; the sulphonamides and penicillin had brought about an altered outlook in the treatment of eye infections.

Dr. Harold Levy, in proposing a vote of thanks, said that Mr. Hine had modestly omitted any mention of his own contribution to the treatment of detached retina, but it had been outstanding. During the 23 years which he had taken as the period of his review knowledge and treatment of ophthalmic disease had progressed out of all recognition, and there had also been a change, perhaps not so marked, in the nature of the cases which came to the out-patient department. The picture of the general affections of the eye which they saw thirty or forty years ago was not quite the same as it was to-day, thanks largely no doubt to better nutrition and to other social factors.

A recent circular from the Ministry of Health to hospital boards and committees outlines the procedure to be followed when they are threatened with legal actions. Proceedings should normally be brought against those bodies and not against the Ministry. If the Ministry is sued it should be informed at once, so that it may have the opportunity through the courts of having the appropriate board or committee substituted for the Ministry in the proceedings. In some exceptional cases it will be appropriate for the solicitor to the Ministry to act in the matter although the proceedings are being taken against a board or committee. The Ministry should be consulted on cases involving the construction of the Act and Regulations, in cases where an application is being threatened for leave to apply for a writ of mandamus, prohibition, or certiorari against the authority, and in cases involving questions of major legal importance. Authorities are not in general authorized to undertake the defence of hospital doctors sued in respect of alleged negligence. If it is sought to make an authority liable for negligent acts of a doctor it should take such steps as are open to it under the Law Reform (Married Women and Tortfeasors) Act, 1935, to obtain a contribution from him in respect of damages that may be recovered. In claims based on negligent treatment by a nurse it is expected that the authority will be sued as her employer, but if the nurse is joined in the proceedings the authority is authorized to see to her defence if she so desires.

Correspondence

Progress in Obstetrics

SIR,—In his enthusiasm to claim rights for the general practitioner that none would deny him, the writer of your leading article (October 8, p. 799) has loosed shafts at all and sundry. The barb directed at obstetricians for having abused caesarean section is both blunt and ill-directed. The medical schools are to be castigated if the new graduate is not "fully competent in obstetric technique"—and presumably surgical technique too. But further on in Dr. Haultain's papers, to which only carefully selected references are made in the leading article, it is pointed out that the student only learns sufficient to enable him to practise obstetrics *under supervision*, and therefore before undertaking domiciliary midwifery the new graduate should spend six months as a house-officer to a maternity unit. From a recent circular it would appear that the Central Health Services Council agree with Dr. Haultain in this.

At the time he wrote these papers Dr. Haultain envisaged that under the new Service the proportion of practitioners refraining from domiciliary midwifery would continue to increase. The speakers at the British Congress were "fearful" because the present regulations provide a financial inducement to the opposite effect. Moreover, the standard of antenatal supervision is dangerously low if two antenatal examinations suffice to qualify the practitioner for payment.

The writer of your leading article is obviously convinced that it is the aim of the obstetric specialist to oust the general practitioner from the sphere of midwifery. This is not true. It is his aim to see that the standard of domiciliary midwifery is kept high and that its practice is confined to those practitioners who are interested and well trained in the obstetric art. Nor does the specialist favour the midwife or encourage her in antagonism to the doctor, for it is obvious that the doctor must maintain his practice of normal midwifery if he is to recognize and treat the abnormal at the midwife's request.—I am, etc.,

S. BENDER.

Liverpool.

SIR,—The leading article entitled "Progress in Obstetrics" (October 8, p. 799) calls for a reply from a teacher in obstetrics. The adequacy of undergraduate teaching is constantly under consideration, and in this university centre as in others the quality of teaching has markedly improved and the quantity greatly increased during the 26 years which have elapsed since I did my student appointment in obstetrics.

Then we spent one month attending the hospital practice, not living in, and a second month attending district cases. I took 11 deliveries, a number at the time above the average, and most of them were on the district. The antenatal clinics at the hospital were not well attended, as less than one-third of the booked cases came regularly; they were for nine months of the year conducted by the resident tutor in obstetrics, a graduate of three years' standing. Only one member of the honorary staff shared in this work, of which she took charge during the remaining three months. Ward teaching and instruction on difficult deliveries were done almost entirely by the tutor, both on the mother and the baby. The tutor was a very good teacher, but we had next to no instruction from senior obstetricians.

Now students do a three months' appointment in obstetrics. During the last quarter the average number of cases taken by each student was 21. Throughout the appointment they live in a hostel adjoining the hospital. Each of the four obstetricians attends his own antenatal clinic each week, and the attendance of the booked patients is not far short of 100%. All emergency cases are written up by the students. There is ward teaching by the professor each week, and the other obstetricians teach in their duty weeks. The professor of child health and his staff conduct regular teaching on neonatal problems. The students obtain most of their cases in hospital, as the district is now much smaller than it was 25 years ago (about 300 cases a year instead of over 1,000). They get about three district cases each. The forceps deliveries, if difficult, are usually taken by a registrar who teaches on them; the easier ones are taken by the house-surgeons under supervision. Sometimes a student may be allowed to do one, but there are not enough for all to get one. It is better to let a limited number of people have a moderate experience, perhaps 10 cases, with the forceps than to let every student, including the potential anatomists, pathologists, and others, have just one each. We hope that most of the general-practitioner obstetricians of the future will have six months' resident experience in a maternity unit. The scheme of teaching is not perfect, but it has steadily improved.

If anyone thinks that it is possible to turn out a competent obstetrician after three months' student instruction he cannot have given a great deal of thought to the question. At the time when I qualified there were in the country large numbers of experienced and skilful general-practitioner obstetricians who gave their assistants a good deal of instruction. I was in general practice for a short time and was admirably taught how to deliver with the forceps by my father-in-law, in whose practice I worked. These skilled men have diminished considerably in numbers, partly because of the increased number of hospital beds and partly because of the larger number of cases taken by midwives. Few practitioners in a city such as Leeds book as many as 30 cases a year. It therefore comes about that a man has much less chance of learning or being taught his obstetrics efficiently in practice than he had 25 years ago. Hence the desire of the Royal College of Obstetricians and Gynaecologists to improve the service by restricting obstetric practice to senior practitioners of experience and those who have had a resident obstetric appointment.

The writer of your leading article appears to take exception to the statement in the *Practitioner* special number that "the average midwife is better trained to deal with normal midwifery than is the average general practitioner." What does he expect? Most midwives in this city book 60 to 80 cases a year, and they spend their whole time in the practice of obstetrics. A few general practitioners may book half these numbers, most of them many less than half. The practitioner, if enthusiastic, may perhaps spend as much as a tenth of his time at obstetrics.

The resident appointment in obstetrics, as in other branches of medicine, can be of great value. It is unfortunate, therefore, that at present few men take one. Usually a man prefers to take an appointment in general medicine or surgery before going into the Forces. For many years now the great majority of our residents have been women, and though it is natural that women should have a special interest in maternity work many of them are soon lost to practice because they marry.

The new graduate in medicine is better trained in obstetrics than his predecessors, but he cannot become skilled unless he has adequate postgraduate experience.—I am, etc.,

ANDREW M. CLAYE.

Leeds

SIR,—Your remarks in your leading article (October 8, p. 799) about the general practitioner's place in the maternity services were long overdue. It is indeed unfortunate that this controversy has engendered a certain amount of resentment on the part of the general practitioner, who feels that the criticisms of his competence are not only unjustified but also unjust, since his own teachers, if not themselves responsible, have at least condoned them.

There must be many general practitioners who until quite recently have had to spend long hours at the bedside taking personal responsibility for normal deliveries assisted only by an untrained handywoman because no midwife was available, and for aught I know there must be many in the remoter parts of the country still doing this. If these doctors have failed to profit by the experience thus gained at the expenditure of so much time and patience it must only be because their teachers have failed to instil into them the fact that every doctor must remain a humble student of medicine until the end of his professional career. It is pertinent to ask where the specialist obtains his experience of normal labour, since, outside the teaching hospitals, most of his normal cases are delivered by his house-surgeons for him. Nor do all house-surgeons

necessarily become specialists, and quite often they go into general practice.

But my purpose, Sir, is not to provide further ammunition for the protagonists in this dispute but to plead that it is not too late to undo the harm that has been done and to try to bring together the specialists, the general practitioners, and the midwives into one team, each complementary to the other and all necessary to the future maternity service. Official policy would seem to be setting out to destroy what vestiges of co-operative spirit remain, and I would humbly suggest that it is ill-advised.

For example, it is the official policy of the hospital boards that in the future the beds under their control in maternity hospitals will be closed to the general-practitioner obstetrician. Surely it would be far better to encourage the general practitioner to deliver primiparae and women with minor types of abnormality in maternity hospitals. It would be an advantage to the patient, whose first pregnancy should be a period of training for future motherhood, to have her baby in proper surroundings, and that her care and training there should be associated with her own general practitioner, for, as you rightly stress, here is the "very root of general practice." It would be an advantage to the specialist to know that those very cases most prone to require his assistance should anything go wrong would be from the first already in an institution suitable for that purpose; this would materially reduce his greatest bugbear, the failed forceps far away in a filthy cottage. It would be an advantage to the midwife, who has to obtain much of her training in such maternity hospitals, to have a ready supply of normal cases for that purpose. And it would be an advantage to the general practitioner himself to know that a select number of his patients can be delivered with all the advantages of modern technique at his disposal.

But above all it would effect an improvement in the whole maternity service, because it would offer a common meeting ground for the keen general practitioner with his colleagues and with the specialists and the midwives with whom he has to work, not only in those casual discussions which inevitably take place in the course of daily visits but in the possibilities for team-work, for regular clinical meetings and discussions, and for staff meetings, and the maternity hospital would thus become a centre for the dissemination of modern teaching and technique.

In due course it would be found that the keenest general-practitioner obstetricians would be anxious to seek opportunities for service in such maternity hospitals, and this would be the means of selecting those who would become most competent and of discouraging the remainder, and thus would bring about the conditions which the Minister of Health is most anxious to encourage. This would be a far more just and equitable method of selecting the best general-practitioner obstetricians than giving this invidious task to a small committee of specialists, who cannot always have the means of assessing the true worth of their more remote colleagues.—I am, etc.,

Wivenhoe, Essex. WALTER RADCLIFFE.

A Year of N.H.S.

SIR,—The review in the *Journal* (October 1, p. 746) of the recently published *Practitioner* dealing with the National Health Service in its first year fails to point out the omission from that journal of any contribution by a worker in the field of preventive and social medicine. The Part III services are referred to only very briefly and incidentally by the medical administrator (undoubtedly a hospital officer) and at somewhat greater length in the paper discussing the Ministry and the Service (almost certainly by a medical officer within that department). This is symptomatic and worthy of note.

It is clear evidence that in the minds of those engaged in Part II and IV services (as represented in this symposium) the Act provides a curative service and not a preventive one. There is no evidence even of the lip service paid in the recent past to social and preventive medicine; there is no reference in the contribution by the young doctors to public health or social medicine as a career—that is significant in itself; no discussion of the difficulties of linking up preventive work with curative work in publicly organized medicine in schools and among young children; no reference to the partial collapse of the school eye service; no reference to the present unsettlement in the public health services; no reference to the absolute exclusion alone among doctors of medical officers of health as such from regional hospital boards.

The obstetrician in his contribution criticizes the general practitioner whom he (collectively) has trained and allowed to graduate, and makes the unpleasant suggestion (unsupported by evidence) that considerations of financial economy have prompted local health authorities to instruct midwives to call in private practitioners early in the pregnancy. A friendly relation between general practitioners and midwives is essential in a world in which specialists are in a small minority, and this is what those local health authorities which are asking midwives to encourage their patients to see their own doctors early in the pregnancy are now trying to secure. The better standard of medical training is, under the General Medical Council, the responsibility of the medical schools with their consultants, and it is a grave responsibility. To improve the obstetric training of both general practitioners and midwives is a better policy and will safeguard the mothers more than by arousing antagonism between them.—I am, etc.,

Dewsbury. E. D. IRVINE.

The Innocence of Deans

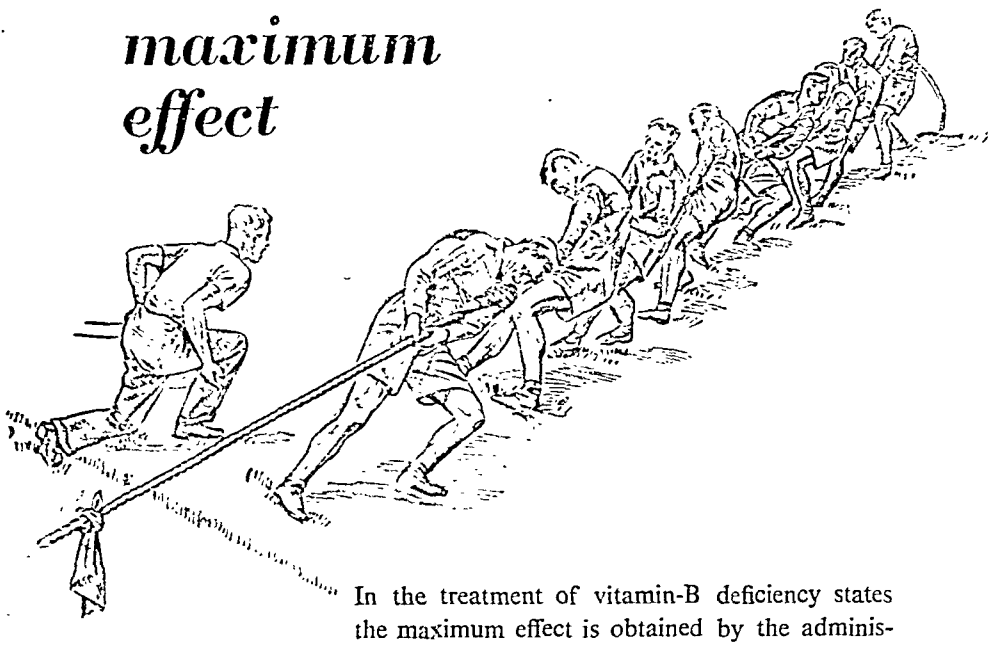
SIR,—Dr. E. R. Boland's letter (October 8, p. 812) is rich in entertainment but obscure in intellectual intention. He apparently misinterprets my feelings towards deans, for whom I have the greatest respect. They work hard, and often thanklessly; they have the difficult job of adjusting situations as between crotchety colleagues; they must arrange teaching programmes, deal with difficult students and refractory committees. In a word, theirs is the art of the administrator and of the politician. Unless "honest and faithful subservience to an institution"—the phrase, apparently, so disliked by Dr. Boland—is regarded by them as their first function, they would fail as deans.

But the crux of the whole State medicine problem is the simple question, Is Medicine to be subservient to politics or is it not? The training and general outlook of a dean, or of a "posse," "clutch," or "diabolry" of deans, would incline them to answer yes. Dr. Boland also, I suspect from the possibly not unintentional irrelevance of his letter, would say yes.

One result of the political direction of a previously free profession is this laughable attempt to assess individual professional status on a points system. Lister, James Mackenzie, Ronald Ross, and indeed most pioneers have usually had their contemporary colleagues against them, particularly so their seniors. If the seniors are unsound judges and if the judgment of the juniors is unacceptable, what judiciary, pray, is there left? Well—I forgot the politicians and the good committee men.—I am, etc.,

London, W.1. GEOFFREY BOURNE.

Modern Trends in Radiology



SIR,—Dr. James F. Brailsford in his article entitled "Modern Trends in Radiology" (October 1, p. 724) indicts modern radiology in medical practice. While the charge may itself be accepted, I feel he is less than just when he cites mass radiography as the arch-criminal. Those who practise mass radiography are, on the contrary, less likely to make the omissions he suggests. I will comment on them in his order.

1. No diagnosis is made or suggested to the patient without a clinical examination whether conducted by the director of the unit, the physician to the chest clinic, or the private doctor. The x-ray film is in fact regarded as an integral part of that examination.

2. Mass radiography provides a unique opportunity of studying the normal.

3. Serial radiography with clinical examination is in no way prohibited because a patient first attended a mass miniature radiography unit.

Towards maximum effect

In the treatment of vitamin-B deficiency states the maximum effect is obtained by the administration of a well balanced preparation containing the vitamin-B complex.

The characteristic symptoms which mild deficiency of this complex produces, including anorexia, loss of weight, constipation and depression, respond rapidly to the administration of Befolin Tablets.

When the diet is restricted or when the dietary intake does not meet an increased demand Befolin Tablets supply the ideal supplement.

BEFOLIN

Each tablet contains :

Aneurine hydrochloride ..	1·0 mg.
Riboflavine	1·0 mg.
Nicotinamide	20·0 mg.
Folic Acid	1·7 mg.

Supplied in bottles of 25 and 100.

Literature on application.

VITAMIN E

To make the administration of large doses of vitamin E more convenient and economical a new strength of 50 mg. 'Ephynal' tablets has been issued in packings of 25, 100, and 500.

'EPHYNAL'

Racemic Alpha-Tocopheryl Acetate

INDICATIONS: According to published and private reports 'Ephynal' is of definite value in the treatment of peripheral vascular diseases and in disorders of the menopause. It is also widely used in the treatment of habitual and threatened abortion and of certain neuromuscular disorders.

'Ephynal' tablets are tasteless and can be chewed or taken with water. They cause no gastric discomfort.

ROCHE PRODUCTS LIMITED

WELWYN GARDEN CITY, ENGLAND

Scottish Depot: 665, Great Western Road, Glasgow, W.2

4. It is true that disease may be present before radiological evidence is apparent, but this applies no more to mass radiography of the chest than to other radiography. In fact the problem arises less frequently, as the vast majority of those attending for mass *x* ray consider themselves, or would be considered on clinical examination alone, to be in good health.

5. Those attending mass *x*-ray units are not treated on the *x*-ray appearances alone but on the whole clinical picture.

There is no belief that active progressive disease is symptomless, nor is this concept part of the propaganda. It is found, however, that people with early active and progressive disease often have symptoms so vague and indefinite that it will not occur to them to consult a doctor, but they will nevertheless volunteer for mass radiography.

It is fully realized that a large proportion of persons who have had active pulmonary tuberculosis do in fact recover from it without knowing of its existence, and this fact will doubtless be emphasized when mass radiography has been with us long enough for a useful follow-up of a sufficient number of cases to establish that such recovery is permanent. Does Dr. Brailsford seriously suggest that no patient with active tuberculosis should be acquainted of the fact or treated until his symptoms are sufficiently severe to force him to consult his doctor? Recognition of ill-health can be as elusive to the patient as shadows on an *x* ray are to a radiologist. How frequently one hears a patient say after treatment, "I thought I was well before, but now I realize how much better I am."

I believe mass radiography may in time, by finding cases in a treatable or pre-infective stage, do much to negative the fear and stigma of tuberculosis which has become established in the public mind by the high proportion of advanced and untreatable cases in our midst.—I am, etc.,

London, S.E.12. F. D. BEDDARD.

SIR,—His colleagues in Great Britain know enough about Dr. James F. Brailsford to discount the various extravaganzas in which he indulged in his article entitled "Modern Trends in Radiology" (October 1, p. 724). Dr. Peter Kerley (October 15, p. 870) has drawn attention to some of the grosser misstatements, and I would merely like to draw attention to the absurdity of his recommendation that medical students should perform upon one another "every kind of injection, including ventriculography, myelography, arteriography, etc." This from the director of radiological studies in living anatomy of a distinguished university.

It is disquieting, however, to learn from a footnote that Dr. Brailsford has been talking such nonsense in various parts of the United States. It is important that our American colleagues should realize that these views are Dr. Brailsford's own and do not represent the consensus of intelligent radiological opinion in this country, and it is with that object that I write this letter.—I am, etc.,

London, W.1. S. COCHRANE SHANKS.

Vitamin Deprivation

SIR,—Professor A. C. Frazer (October 1, p. 731) should be congratulated on his conception of a new mechanism in the explanation of vitamin deprivation. The idea of bacterial invasion of the upper small intestine is not novel, and I myself reviewed the literature both for pernicious anaemia[1] and for the sprue syndrome[2] some years ago. Professor Frazer's great merit lies in putting forward the hypothesis that the periodic increase of bacterial invasion into the higher small intestinal regions might result in competition between bacteria and host, leading in many cases to signs of deprivation in the host.

While there are reasons to believe that the deficiency of the vitamin-B group may be connected with interference of absorption in general,[3] Professor Frazer adequately proved that this is not intimately related to the fat-absorption defect in sprue.[3] Many will agree that the competition hypothesis—if this should be proved in the future—might account for the exacerbation of some vitamin deficiencies in general, for selective deficiencies often observed in the sprue syndrome, and also for many other conditions suggested by Professor Frazer. I have, however, some doubts as to the statement that it might explain the administration of one vitamin precipitating the deficiency of another.

The considerable literature dealing with vitamin imbalance contains many well-documented cases where a bacterial invasion of the higher small intestine was most improbable.[4] It has been suggested, when discussing the aetiology of the sprue syndrome, that phosphorylation constitutes an important link between sprue and the B vitamins.[3] It was found later by Magyar that the consumption and excretion of these vitamins were dependent on phosphorylation.[5] The same author reported recently experiments on rats showing that previous administration of a large dose of any of the main members of the vitamin-B group interferes greatly with the absorption of a standard dose of thiamin. He attributes his findings to the exhaustion of the phosphorylating capacity of the animals.[6] Further experiments will have to decide whether this is the real explanation of vitamin imbalance as it is claimed.

This comment is not meant to detract from the importance of the competition hypothesis, and it is hoped that the Birmingham workers will further elaborate this conception.—I am, etc.,

Infant Vaccination

SIR,—In the current issue of the *Monthly Bulletin of the Ministry of Health* (1949, 8, 204) Dr. E. T. Conybeare, of the Ministry of Health, gives a report on the amount of infant vaccination in England and Wales during the six months July–December, 1948. He shows that for this period, the first half-year under the new Act, the proportion of infants vaccinated has fallen to about half what it was before the Act came into force. He concludes his article by saying:

"If the figures for 1949, when they become available, show that the decline of infant vaccination under the National Health Service is not temporary, measures, such as an increase in the number of vaccination clinics . . . and the working out of some plan to facilitate domiciliary infant vaccination in areas not served by such clinics, may be urgently required. Such measures, pursued with the energy put into the campaign for immunization against diphtheria, might well produce similar results and make the child population of this country as well vaccinated as that of the United States or other countries, where protection against smallpox is regarded as the important matter that it undoubtedly is."

Is not Dr. Conybeare rather begging a highly debatable question when he makes that final assertion? Is a well-vaccinated child population really such a very important matter in protecting a community such as ours against smallpox? Surely there is a great deal of valid evidence pointing to the opposite conclusion. Decline in infant vaccination is not a new phenomenon. It has been going on continuously for over half a century, but so far from its having been followed by any increase in smallpox mortality the latter has fallen steadily, until now it is practically negligible. Moreover, in those parts of the country where the decline in infant vaccination has been greatest the same decrease in smallpox mortality has been witnessed. Thus in the city of Leicester the average percentage of infants vaccinated has for very many years been under 5 (Dr. Conybeare tells us that it has now fallen to 1.4%), yet during the past 40 years there have been only two deaths from smallpox, and other places have had a similar experience.

After all, it is the adult population who are most exposed to the danger of smallpox, and the effect of infant vaccination in protecting this section of the community is very doubtful. It may reasonably be argued that infant vaccination by masking the disease in adults, when the protection conferred on the individual is wearing off, neutralizes—or more than neutralizes—any value to the community derived from the partial immunity conferred on the individual adult. Incidentally, it may be mentioned that in the 14 years 1932–46 there were in England and Wales only 28 smallpox deaths (an average of two per annum

in a population of 40,000,000), and not one of the fatal cases was under the age of 1 year. Yet in the same period there were 51 deaths from vaccination under 1 year of age.

Dr. Conybeare mentions admiringly the United States and "other countries." What other countries, including U.S.A., can show better results in dealing with smallpox than Great Britain? So I venture to suggest, with all respect to Dr. Conybeare, that perhaps, after all, infant vaccination is not such a very important matter in protecting a community such as ours as he seems to think.—I am, etc.,

Leicester. C. Killick Millard.

Malignant Tertian Malaria

Sir,—In his address on the treatment of malignant tertian malaria Sir Gordon Covell (October 8, p. 773) gives an excellent and comprehensive survey of the present position as regards therapy. In his discussion of diagnosis and symptomatology, however, there is much that many practitioners with long experience of malignant tertian malaria will disagree with. Sir Gordon repeats the warnings about the difficulties of diagnosis—the statement that M.T. malaria may "simulate a great variety of other diseases"—which are to be found in every textbook since Manson's original *Tropical Medicine*. He repeats the classification into cerebral, algid, bilious, remittent, and cardiac forms, which appear to me to be singularly useless and misleading.

Is M.T. malaria really a very difficult disease to diagnose? Does it really imitate other diseases to such an extent? Is it not possible that this view is based on a fundamental fallacy which arose in the early days, when the finding of the recently discovered M.T. parasite in the blood stream of white, black, and brown patients was hailed as the explanation of all their symptoms? Has not a process of disentanglement been in operation over the past quarter-century?

Sir Gordon refers to a series of 80 cases of British soldiers treated by him at Nairobi in the 1914–18 war. They arrived from the Lake Victoria district. All showed M.T. parasites in their blood, but some showed symptoms suggesting dysentery, typhoid, biliary colic, etc. All responded to quinine and hospitalization. I fail to see how this proves the versatility of malarial symptomatology. Surely it is at least possible that some of those troops, under the conditions obtaining, had other diseases besides malaria—bacillary and amoebic dysentery, for instance. Is it not possible that some had double infections of M.T. and quartan? Knowing that area well, I would say it is more than possible.

My own experience in Africa has convinced me that there has been a great deal of nonsense talked about the "protean" nature of M.T. malaria and its so-called pneumonic, dysenteric, appendical, and other "forms." In some thousands of European cases I have treated I have seen a few where malaria was complicated by pneumonia, by dysentery, and by other infections, but I would say that in the main M.T. malaria presents a remarkably constant clinical picture (more so than quartan), besides being quite easy to diagnose in the vast majority of cases. I would say that great harm can be done by teaching young practitioners going to the Tropics that they may have serious difficulty in distinguishing malaria from appendicitis. I have seen only three cases where such difficulty might have arisen. In two of these I removed acutely inflamed appendices in the middle of typical blood-positive malarial attacks. In the third the patient formed an appendical abscess after his malaria had subsided. Nowadays, when I read about appendical forms of malaria, I do what the man in the *Ingoldsby Legends* did: I say no word to indicate a doubt, but . . . Sir Gordon rightly emphasizes the dangers of delay in diagnosis, but his two illustrative cases merely show the effect of *gross* delay and provide two typical histories of untreated M.T. malaria. There was apparently no difficulty in diagnosis, nor were there any extraordinary symptoms. I do not think they should deter anyone from delaying for a short time, unless the case is dangerously ill when first seen or is a young child, in order to establish a microscopical diagnosis. Sir Gordon states that "in a primary case parasites may be so scanty in the peripheral blood during the first few days of fever that they may not be detectable in a blood smear, even if no antimalarial drug has been administered." This is not my experience nor, I am sure, that of many others. If antimalarial drugs are withheld in a patient showing pyrexia, and blood examinations made at intervals over 48 hours, I believe that parasites will be found practically invariably if M.T. malaria is the cause of the pyrexia, and I believe this to be a perfectly safe procedure to adopt. Sir Gordon's method of giving an antimalarial drug after examination of one smear and waiting for the temperature to drop before taking another would tend to confuse rather than clarify diagnosis by making the parasites more difficult to find. Moreover, in a first attack of M.T. malaria the temperature is very unlikely to drop for four to five days even when treated intensively—another very constant feature of this "protean" disease.

In short, I would advise practitioners going to the Tropics not to be too much impressed by classical descriptions of M.T. malaria. (If they do native work they will soon learn not to ascribe a native's pathology to malaria parasites in his blood.) I would advise them to put the greatest reliance on the microscope for diagnosis and not to be put off intelligent use of it for fear of dire calamities, to beware of ascribing atypical symptoms to a disease which follows a very typical course, and to operate on patients who show signs of acute surgical conditions even if there are M.T. parasites in the blood. In modern tropical European practice there is much more harm and confusion caused by ascribing to malaria all manner of symptoms when it does not exist than by failing to recognize it when it does.—I am, etc.,

Craven Arms, Shropshire. P. Ross.

Poliomyelitis

Sir,—Your correspondent, Dr. N. G. Nicholson (October 1, p. 757), describes a series of cases of non-paralytic poliomyelitis occurring in Colombo, and then details his own unfortunate experience. His description of his own symptoms, in particular "the most terrific pain I have ever experienced in my left shoulder" and the delay in appearance of muscle wasting, is quite characteristic of acute brachial radiculitis, or the "shoulder-girdle syndrome."[1,2]

It is interesting to note that Parsonage and Turner[2] describe a case of coincident poliomyelitis and the shoulder-girdle syndrome, and I myself have seen a rather similar case in which the syndrome developed two weeks after an abortive attack of poliomyelitis. The pain in the affected muscles is much more severe in acute brachial radiculitis than I have ever encountered in poliomyelitis.—I am, etc.,

Harrogate. R. Harris.

Poliomyelitis Vaccination

Sir,—Mr. M. H. F. Johnson (October 1, p. 757) has raised an important point in asking why, following the lead of Jenner and Pasteur, active immunization against poliomyelitis is not practised. It has been shown by Kolmer[3] and Brodie[4] that the vaccination of monkeys with living attenuated ricineolated or formalized virus, prepared from the spinal cord of a monkey after serial passage, produced an active immunity sufficient to enable them to withstand intracerebral inoculation of infective doses of virus. These experimental results immediately suggested that a vaccine suitable for human use was feasible.

Field trials with poliomyelitis vaccine have unfortunately been inconclusive, due largely to administrative difficulties. The low morbidity of poliomyelitis (an attack rate of 1 in 1,000 even during epidemics being exceptional) necessitates the immunization of many thousands to show any significant statistical results. Furthermore, it is now accepted that many different strains of poliomyelitis virus exist, some of which show antigenic inter-relationship while others appear antigenically distinct. The experiences of Gillam and Ornstroff[5] and Reynolds and Knox[4] illustrate the difficulties of field trials. These workers together vaccinated 1,000 children, another 1,000 being used as controls. No case of poliomyelitis developed in any of the 2,000 children employed.

The fact that poliomyelitis vaccination is not devoid of serious danger has been shown by Leake,[5] who collected a series of 12 cases; five of the patients died and three of them were left severely paralysed after vaccination. The clinical onset of the disease occurred within 6–14 days of either the first or the second inoculation—i.e., within the accepted incubation

period. Leake, after a careful analysis of all attendant circumstances in these cases, points out: (1) Poliomyelitis was not epidemic in any of the areas where these cases occurred. (2) The expectation of poliomyelitis among the vaccinated, judging by its occurrence by age groups in the community at large, was less than 1/10 of a case in these localities, yet cases occurred. (3) The likelihood of the whole series of cases having occurred by natural causes was extremely small. (4) In none of the cases was exposure to infection outside its own area known to be of any special significance. (5) In every case in which the sequence of events was known, the level of the spinal cord first affected corresponded to the limb in which the injection was made, paralysis beginning either in the same or in the contralateral side. While any one of these cases may have been entirely unconnected with vaccination, the implication as a whole is clear.—I am, etc.,

Manchester. W. P. SWEETNAM.

Lead Nipple Shields

SIR,—Shades of Dr. Wansborough! Little did that worthy if imaginary gentleman think when he "invented" his nursery requisite about 50 or 60 years ago that he would cause such apprehension and alarm in 1949. Yet I have no doubt his intentions were kindly and well meant, for these 3-in. (7.5-cm.) disks of thin, smooth metal, carefully shaped to fit the contour of the nipple snugly, like a little conicle-crowned broad-brimmed hat, and with as much zinc as lead in their composition if one may judge from their lightness and shape-retaining qualities, were worn on the nipples between feeding-times and during the night, and removed, of course, when the child was put to the breast.

The Minister of Health reasoned, no doubt correctly, that during the longer periods of rest and warmth the film of milk around the nipple and imprisoned by the shield would turn slightly sour, forming an infinitesimal amount of lead lactate, thus exerting *in situ* a very mild, soothing, and astringent action on the macerated and tender part, akin, as it were, to the same beneficial effect that liq. plumbi subacet. dil. (Goulard's water) has when used as a dressing on moist excoriated surfaces. As regards the risk of lead-poisoning, surely the ordinary instincts of cleanliness would prompt the mother to cleanse the breasts and shields, if not before each feed, at least once or twice daily. However, the Ministry has apparently some startling news for us, and has promised the publication at an early date of the full details of how babies can absorb such an amount of lead by this means as to cause saturnine encephalopathy, a state of poisoning which as a rule, in my experience, indicates a severe saturation with the metal. Let us hope the mothers have not been excreting diachylon taken in the early months of pregnancy.

But apart from the foregoing, who in all the earth prescribes lead nipple shields nowadays? I saw them 40 years ago when in business, and the pair we had then were real museum pieces, marked for many a day as dead stock and quite unsaleable. In this town of 50,000 inhabitants not a single one can be bought. There are 18 chemists—principals and staffs totalling about 100—all handling N.H.A. scripts. Out of these, three had actually seen lead nipple shields many years ago, eight apparently knew about them, and the remainder had never heard of them at all. The same circular from the Ministry has been sent to them too, each one wondering what it is all about.—I am, etc.,

Lancaster. R. G. HOWAT.

SIR,—The announcement in the Press of the Ministry of Health's embargo on the use of lead nipple shields has only just brought to my notice this controversy. Like many women handicapped by severely cracked nipples, I have reason to be grateful for this effective aid to breast-feeding: when all other remedies failed lead nipple shields enabled me to feed each of three babies for a normal period of nine months. If the breasts are thoroughly washed before each feed it is difficult to see how the babies can suffer.

I should like to examine some evidence before I acquiesced in the Ministry's fiat and abandoned the shields for a fourth child, which would inevitably mean weaning at a few days old—in my view a tragedy. I could, with difficulty, obtain a pair of shields from France, where they have been in common use for generations, but such a course of action, in opposition to the full weight of medical opinion in this country, would be a terrifying responsibility for any mother.

Can you tell me where the evidence which led to the Ministry's decision can be examined? And can you perhaps influence the public press to publish the source, so that women can test such evidence against their own experience before making a very difficult decision?—I am, etc.,

Barnstaple, Devon. JOAN S. BLACKSELL.

*** In the *Lancet* of October 8 there is a paper (p. 647) by Dr. I. Gordon and Mr. T. P. Whitehead entitled "Lead Poisoning in an Infant from Lead Nipple Shields" and a letter (p. 674) by Drs. Helen Mackay and Donald Hunter on the dangers of lead nipple shields.—ED., *B.M.J.*

Congenital Pyloric Stenosis

SIR,—The occurrence of congenital pyloric stenosis in three consecutive children in a family is not so unique as Dr. J. L. Adlington (October 1, p. 740) suggests. Brendle[1] records its occurrence in three brothers in the same family, and Fabricius and Vogt-Muller[2] described its occurrence in all four children of the same mother, three of whom had the same father. I saw three consecutive children (two girls and one boy) of the same parents who were successfully treated by "eumydrin" at the Leicester Royal Infirmary. These cases—Nos. 44, 57, and 103—were included in a series of 112 cases of pyloric stenosis admitted over a period of eight years and reported in *Archives of Disease in Childhood* (1947, 22, 75).—I am, etc.,

Liverpool. R. MCLAREN TODD.

Symptoms of Psychoneurosis

SIR,—The results of an investigation briefly described below may be of some interest. The symptoms were studied of two groups of medical out-patients and of one group of in-patients on whom the physician's opinion was asked. The 672 patients were seen during Naval service and were mostly men of the Royal Navy and R.A.F. Two-thirds were between 17 and 35 years of age.

A diagnosis of neurosis was made in 31% and 30% of the two out-patient groups and in 24% of the in-patients. When those patients were included whose symptoms were mainly neurotic the percentages were 38, 36, and 34 respectively, with an average of 36% (244 out of 672 patients). Pain was the commonest symptom in these 244 and was complained of by two-thirds of them, often in more than one site. It was a more common symptom in these people than in a sample of non-neurotic patients. In half of those complaining of pain the pain was a headache. One-third of the 244 complained of dyspnoea of some sort (on exertion, on lying down, waking up panting for breath, a feeling that the chest could not be filled, etc.) and one-third complained of insomnia. One-quarter complained of tiredness (weakness, exhaustion) and one-quarter of giddiness ("dizziness"). One-sixth complained of either trembling, palpitations, precordial pain, or abdominal pain. Only about 5% complained of loss of confidence or of loss of concentration or of irritability.

Twenty-two of the 244 patients suffered from a cardiac neurosis. This proportion (9%) is much less than that found among neurotic patients in the Army.[1,2] Fifteen patients may be said to have had a pulmonary neurosis. Fear of tuberculosis appeared to be the commonest cause of this. Eleven had mainly genito-urinary symptoms (enuretic patients without

other evidence of neurosis were not included in the 244). Two patients had a neurosis simulating rheumatism. One-third of the neurotic and mainly neurotic patients gave a family history of psychopathy according to Slater's definition[3] as against 5.9% of the non-neurotic patients.—I am, etc.,

Rochester, Kent. F. A. Richards.

Tetraethylthiuramdisulphide in the Treatment of Alcoholics

Sir,—I was most interested to read Dr. A. E. Carver's article on the treatment of alcoholics with tetraethylthiuramdisulphide (August 27, p. 466). I have used the drug in more than 50 cases of alcoholism during the past eight months, and I fully agree with Dr. Carver's conclusion that it is a useful ancillary in the treatment of this serious and troublesome illness.

Dr. Carver describes two methods of the administration of the drug—either to give it surreptitiously without the patient's knowledge or consent, or to give it after a full explanation with the patient's co-operation. I consider that the first method he describes is dangerous. I have observed a few very severe reactions following the ingestion of alcohol in sensitized patients which, if they had occurred in the patient's own home or in public, might have led to serious consequences.

On a recent visit to Scandinavian hospitals, where the drug is widely used, several deaths following the treatment were reported to me. Jones[1] has reported very fully the case of a healthy young male who died a few hours after taking a test dose of an ounce of rum, following premedication with tetraethylthiuramdisulphide during the previous four days. It is clear, therefore, that this is potentially a dangerous drug unless its administration is carefully controlled.

The patient's reaction to alcohol when taking the drug should not be left to chance, but a test should be carried out under hospital conditions. It is wise, too, to inform the patient and his relatives that alarming symptoms may follow the ingestion of alcohol, and that a clinical trial with a small amount of alcohol will be made to test out his reactions before he is allowed to run the risk of drinking at his own discretion. Unless these precautions are taken I feel there is a danger that this valuable adjunct to the treatment of alcoholism will fall into disrepute.

I am surprised at Dr. Carver's suggestion that the drug should be given only for a month or two. It is surely a matter of clinical experience that an alcoholic must be considered prone to relapse until he has been abstinent for a very much longer period.—I am, etc.,

Dublin J. N. P. Moore.

Treatment of Varicose Veins

Sir,—Mr. C. H. Wickham Lawes has misread and misquoted me; and, moreover, his otherwise courteous letter (September 24, p. 708) has given no less provocation by his repeated "of course"—a term that I hope you will allow me to show fits too loosely to his arguments about a matter of some importance. He has "tried most methods including Dr. Hanschell's (it is, of course, not new)." In my letter (March 19, p. 500) I gave a summary of this method, brief yet sufficiently precise to be intelligible and identifiable. It is not new, in so far as I arrived at it very slowly over a period of years by trial and error and comparison with controls; have practised it for a decade; and find it adopted by colleagues. It is new only in that no one else has yet described it (nor have I, fully, in boring detail). I take leave, therefore, with due respect to Mr. Lawes, to doubt whether he knew of it, "of course," or anyhow, or has in fact tried it; and I beg him to extend his courtesy to re-read my letter with closer attention.

Again, "Dr. Hanschell states" that minimal injections give extra pain and longer convalescence, and that sclerosant injection is a dangerous ally and a useless one. Of these statements Mr. Lawes writes, "Of course they are far from correct." But, Sir, what I wrote was to the effect that he would find his minimal injections, as ally to ligations, had served only to give a pain and convalescence respectively extra and longer than that attached to ligations alone in control legs. How correct that is, Mr. Lawes can know "of course" only if he (as I had) tried those controls—and he hasn't. I wrote that sclerosant injection was dangerous *or* useless, not *and* useless. The difference in a serious discussion is not unimportant. Will not Mr. Lawes oblige by re-reading my letter? Furthermore, he states, "Operation or injection alone is not enough." Which certainly confesses that the uselessness of injection alone is not "of course far from correct."

Now it has happened that some (however few) deaths have resulted from "the method of choice . . . a combination of operation and injection." I suggest it is not "of course far from correct" to find here a not dubious implication that some injection, although not enough alone, may be dangerous enough as an ally to operation—and the plain corollary that this ally injection to be safe must be useless. I have no doubt that Mr. Lawes will have more than glanced at Sir Heneage Ogilvie's restrained damning (September 24, p. 665), on the facts of observation (and how timely), of this ally injection. I have given facts of observation, that any one may find for himself, to speak for themselves. "My opinion" would be supererogatory pomp, uncomplimentary to a professional brother and unbecoming to me. It would be, of course, far from correct to pretend that a death here and there, following this or that induction of thrombophlebitis, made a holocaust: but it has made more than one dead human, who would not have died of varicose veins.—I am, etc.,

London, W.1. H. M. Hanschell.

Serous Fluid in Wounds

Sir,—After certain operations it is common to find an accumulation of serous fluid in the wound. This is usually of minor degree, but on occasion the effusion may be gross, persistent, and have the characters of a lymphatic fistula. Such is occasionally the case after a radical mastectomy, after dissections of the lymphatics of the lower neck, and after dissections of lymphatics in the groin and upper thigh. If the leakage does not cease spontaneously or respond to simple measures such as firm strapping, the condition appears readily curable by the injection of one of the sclerosants used for the treatment of varicose veins.

Exploration of such wounds shows, after about 10 days, a cavity lined with granulation tissue. No doubt there is by this time a very definite walling-off by the granulation-tissue barrier and fibrosis deep to it. The method used would therefore appear safe, providing the wound is not clinically septic. Apart from its use after mastectomy and similar operations I have used it with success in a case of pancreatic fistula. As illustrating the method, the following case may be quoted.

An elderly woman, two weeks after radical mastectomy, was having over 600 ml. of serous fluid removed from the wound, by probing and pressure, each day. The skin wound was well healed and the evacuated fluid not purulent. A rubber catheter was introduced into the cavity as far as it would go and all the fluid evacuated. Monoethanolamine oleate solution (15 ml.) was then injected via the catheter, the catheter removed, and the chest wall firmly bandaged. Twelve hours later the patient complained of some burning pain. A catheter was inserted and the cavity irrigated with normal saline, stringy clots of exudate being thus removed, along with, presumably, surplus sclerosant. A firm dressing was applied for 48 hours. There was no further discomfort, no visible reaction, and no further accumulation of fluid. The patient was discharged a few days later.

Both monoethanolamine oleate and "ethamolin" have been used. The amount required varies with the size of the cavity—from 5 to 15 ml. It is seldom necessary to repeat the treatment. The above case is the only one in which irrigation to remove surplus sclerosant and debris has been necessary—if indeed it was.

It would appear that the treatment acts in two ways: first, by the coagulation of albuminous fluid a stringy tenacious jelly is produced which glues the walls of the cavity together and occludes open lymphatic channels; secondly, the irritation of

the cavity walls enhances the effect and probably aids adherence of the gel. No general or regional reaction has been observed. The number of cases treated has been small, and one feels that the treatment should be used with care and discrimination. The method has proved most satisfactory in my experience. I do not imagine it to be at all original, but as I have not seen it recorded it seems a pity not to make it more widely known.—I am, etc.,

Dartford Kent. STEPHEN BARCLAY.

Streptomycin in General Practice

SIR,—It is very pleasing that the production of streptomycin has so increased that the supply and distribution of the drug no longer require to be organized by the Ministry of Health through various "key" hospitals. Under new regulations coming into force in November streptomycin will be available to all on prescription. It has, however, been the experience locally, and no doubt the same has been the case elsewhere, that in recent months there has been no difficulty in obtaining adequate, prompt supplies of streptomycin for all those cases of tuberculosis encountered at the chest clinic and in hospital who may be expected, in the light of present knowledge, to be benefited by the treatment.

In view of the prolonged course of many forms of tuberculosis and the fact that cases of advanced or chronic phthisis may have to wait nearly a year for hospital treatment, or may never be admitted to an institution because of the shortage of beds, it seems likely to me that many general practitioners will be moved by the laudable desire to do something for their patients to prescribe streptomycin in cases not really suitable. Where general practitioners hesitate, some may be pushed into this course by anxious patients who have heard of the wonder-working medicine.

Apart from possible toxic effects, a very great danger exists in the frequent development of resistance to streptomycin in the tubercle bacilli. If chronic pulmonary cases are given prolonged courses we may find that without benefiting the patients we have produced chronic carriers of streptomycin-resistant bacilli. Any new patients infected by them with these bacilli, and as a result suffering from miliary, meningeal, or other forms of tuberculosis previously responsive to streptomycin, will be unable to be helped. They will have to get better without the help of streptomycin. The meningeal cases will die, and the chest cases will further spread the resistant bacilli. In short, we shall be back where we were five years ago.

It is significant that in the official notice published in the *Journal* of October 1 (p. 752) it was found necessary to give advice on the proper use of streptomycin. I feel, however, that it is too much to expect of general practitioners that they will entirely refrain from using streptomycin in those cases of chronic or advanced disease which form the majority of the tuberculous patients whom they have to treat at home.

I would suggest, therefore, that it would be better for all that the use of streptomycin should depend upon a hospital physician's prescription, just as have been, I understand, less potentially dangerous remedies such as surgical trusses for herniae and physiotherapeutic measures. I hope the responsible bodies will act in this matter.—I am, etc.,

Welwyn Garden City, Herts. B. COUTS.

POINTS FROM LETTERS

Transitory Retrobulbar Neuritis

Dr. HORATIO MATTHEWS (London, W.13) writes: Your critic (September 17, p. 662) is a bit too severe. In my 40 years of eye work I have on several occasions come across transient depreciation of visual acuity following local sepsis. In one case the patient was a G.P. whose visual acuity fell in the right eye from 6/6 to 6/9 with obvious embarrassment within a week of removal of a meibomian cyst from that eye. And there are many I could recall associated with sinus infections. I do hope too much emphasis will not be laid on hysteria. The diagnosis of ? mild or axial or macular retrobulbar neuritis is involved anyway. Is it possible that the whole business is not retrobulbar (in most instances) but microscopically macular ?

Obituary

JAMES KYLE, M.R.C.S., L.R.C.P.

Air Commodore James Kyle, for the past four years assistant director of medical services of the British Overseas Airways Corporation, died suddenly in St. George's Hospital on October 8. He was born in 1888, and was educated first at Watson's College, Edinburgh, and later at Shrewsbury. He studied medicine at Guy's Hospital before the first world war, but left his medical studies in 1914 to serve as a combatant in the Artists' Rifles. He was gassed in France and returned to his medical school at the end of 1916, taking the Conjoint diploma in 1918. After qualifying he was for a short time an assistant medical officer at Lambeth Hospital. In the Royal Air Force, in which he served as a regular officer from 1919 to 1945, he held many important posts.

Sir Harold Whittingham writes: "Jimmy," as he was known in the Royal Air Force and among his wide circle of friends, was commandant of the Medical Training Establishment and Depot just before the war and during most of the war period. Here he was to a large extent responsible for the high ideals instilled into the R.A.F. medical officers and medical orderlies which did so much to mould their characters and to build up a medical service which won great distinction during the recent war.

Kyle had natural charm and grace, and was good-humoured, kind-hearted and generous, possessed of much common sense and a breadth of mind that always appreciated and gave due consideration to the other person's point of view. He was calm, tactful, and outstandingly loyal, and was an ideal administrator beloved and respected by his colleagues, staff, students, and all who had to deal with him. Some eleven years ago he had a severe attack of coronary occlusion. Despite this he bravely and unflinchingly carried on onerous duties in the Service throughout the war and, after his retirement from the Royal Air Force, in the medical service of the British Overseas Airways Corporation, playing a prominent part in its establishment and administration. In addition he undertook the duties of R.A.F. representative on the Armed Forces Committee and on the Council of the British Medical Association. In this committee and at all times he worked hard to improve the conditions of the medical service of the Royal Air Force, which he loved so well. Those of us who have been privileged to serve alongside him for the past thirty years cannot speak too highly of his contribution to Service and aviation medicine, nor of the value of his friendship, help, and advice. We wish to express our deepest sympathy with his wife and two daughters in their great loss.

Dr. JAMES MCALISTER RAMSAY died in an Edinburgh nursing-home on July 26 at the age of 79. He was born in Airdrie, Lanarkshire. It was originally intended that he should be a schoolmaster, and he did some teaching, but his heart was in medicine. He obtained the triple qualification of Edinburgh and Glasgow in 1896, and after preliminary assistantships in Sheffield and Glasgow he took up practice at Parkhead in Glasgow. He built up a successful practice and continued his work there until 1914, when he was appointed medical officer to the Fife office of the Mineowners Defence and Mutual Insurance Association, Ltd. In the exercise of this office he came in contact with most of the doctors practising in the mining areas in Fife and earned their respect and esteem. He was a popular examiner for the St. Andrews Ambulance Association, having the knack of putting candidates at their ease and drawing the best out of them. He was made a J.P. in 1930,

Dr. Ramsay retired in 1945 and came to live in Limekilns, a village outside Dunfermline, where he took part in all the social activities of the village and formed a new circle of friends. He kept his hand in professionally by occasionally deputizing for the local doctor, and he was always ready to give of his best in any emergency. He was a cultured, genial, and kindly man, and his passing is regretted by all who knew him.—R. C. W.

Dr. JOHN PRIDMORE RABAN died in Bristol on October 2 at the early age of 44. Born at Harpenden, Hertfordshire, he received his medical education at the Middlesex Hospital, taking the Conjoint diploma in 1929. After an appointment as house-physician at St. James's Hospital, Balham, he returned to the Middlesex, where he became in turn house-surgeon to Sir Gordon Gordon-Taylor, to the ear, nose, and throat department, and to the gynaecological and midwifery department. It was then that he decided to make radiotherapy his specialty, and he was appointed to what has since become the Meyerstein Institute of Radiotherapy. He took at this time the D.M.R.E., and continued to gain experience until the outbreak of war. In his student days John Raban had been a keen member of the University of London O.T.C., and on qualifying he took a commission in the R.A.M.C. (T.A.), assuming command of the company composed of cadets from the Middlesex and St. Mary's. The training and seniority so gained stood him in good stead during the war years. After a period as radiologist to a general hospital in India, he was given command of one of the first two units of its kind—a Forward Malarial Treatment Unit. Following inevitable teething troubles, this unit moved into the Burmese jungle, where its operational success was outstanding, and recognition of this was accorded by John Raban's mention in dispatches. His final war appointment was to the command, as full colonel, of a general hospital in Ceylon. In 1945 he returned to the Middlesex as first assistant in the Meyerstein Institute, and subsequently was appointed radiotherapist to the Bristol Royal Hospital. With the change of administration in July, 1948, his sphere became that of the United Bristol Hospitals. It was soon after his return to civilian life that his health began to fail, and there can be no greater testimony to his courage and tenacity of purpose than the success he made of this responsible task against increasing odds. He stuck to his job until a few days before his death. John, as he was affectionately known to all colleagues from the most senior to the most junior, never made any claim to academic brilliance. But this was more than offset by a fund of common sense, of human understanding, and an ever-growing clinical intuition. His judgment was respected by all. His was a strong character which enabled him in all circumstances to speak his mind, and was shown perhaps best in his great qualities of leadership. In both war and peace he earned the respect, loyalty, and friendship of all those who served under him. He was blessed with a great sense of humour, and he loved gaiety. These latter qualities were shown in a most successful series of amateur revues which he produced and took part in during his earlier days. He also enjoyed his sport, being a keen horseman and playing for his hospital at rugger. Those who knew him will feel the world a poorer place for his departure. He leaves a widow.—L. C. B.

Dr. S. Curwen writes: I shall always remember John Raban for his great quality of trying to make life as easy as possible for others. A more selfish man could well have preserved himself, but John, with that apologetic way of his, was always so anxious to pull his full weight that he wore himself out.

Dr. KENRICK STANTON WISE, whose death was announced over a year ago, was Surgeon-General in British Guiana from 1914 to 1919, and in Trinidad and Tobago from 1919 to 1936.

A former colleague of his, Dr. J. E. A. Boucand, writes: Dr. Wise arrived in Trinidad just in time to introduce fundamental changes aimed at improving the efficiency of the health services. His was the task of putting into effect the Public Health Ordinance of 1915. Also in 1919 he was appointed chairman of a local committee to inquire into the organization of the medical service. The main recommendations of this committee provided for increases in personnel and in the salaries of medical officers and nurses. As a result of further requests for an improved service, in 1932 another committee with Dr. Wise as chairman was appointed. The report of this committee showed evidence of a very searching inquiry and contained recommendations affecting all branches of the health service. Dr. Wise resigned from the Service in 1936, and was therefore unable to witness the implementation of these recommendations. During his long term of office lepers were transferred from the mainland to a settlement on an island, Chacachacare, where the inmates benefited from the most modern advances in the treatment of leprosy, and their life was made generally more agreeable. The domiciliary treatment of non-infectious cases was encouraged. Dr. Wise was responsible for the setting up of a new "House of Refuge," a modern institution for the treatment and care of the aged and destitute. He urged with success the provision of facilities for postgraduate study, improved the training of nurses, and stressed the need for residential accommodation for nurses. He made great efforts to have a sanatorium established, and formulated the first plans for renovating and extending the Colonial Hospital, Port of Spain, and for rebuilding the Colonial Hospital at San Fernando. He introduced the ear, nose, and throat clinic, the eye clinic, the dental clinic, and a venereal diseases clinic, and was a strong advocate of the medical inspection of schools and of intensification of antimalarial work. He was an able pathologist and born administrator, realistic in his outlook. He was a quiet thinker, with a ready grasp of the most difficult problem. He did much for the West Indian doctors and nurses, but failed in his endeavour to establish a school of dispensing in Trinidad. A man of decision, with a great respect for the opinion of others, he had a fine understanding of human nature, and was able to assess at their true values the officers in his department. Dr. Wise lived a quiet life in the Colony, retreating every week-end to his country seat at Morne Bleu. He spent his leisure moments in the study of history, and was the founder of the Trinidad Historical Society and its first president. His ability and public service were recognized by his appointment to the Executive Council of the Colony. Great regret and sorrow were felt when news of his death in London belatedly reached the Colony he served so well and where he left so many lasting memories.

Medico-Legal

OVERDOSE OF NITROUS OXIDE

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

A married woman of 38 underwent a minor operation on a septic thumb at the Adelaide Hospital, Dublin, under nitrous oxide and oxygen anaesthesia. The oxygen cylinder was empty, and the student nurse who was assisting was sent for another. She brought from the rack outside the door of the theatre a cylinder which contained, not oxygen, but nitrous oxide. After a few minutes the woman house-surgeon who gave the anaesthetic noticed that the patient was slightly blue and turned off the cylinder which she knew to contain nitrous oxide, but left turned on the new one, which she in error thought to contain oxygen. It was then discovered that this, too, was a nitrous-oxide cylinder. The mask was removed and artificial respiration was continued for two hours, but the patient did not recover consciousness. An account of the inquest[1] on May 31 appeared in this section of the *Journal*.

The prosecuting authorities summoned the house-surgeon[2] before the Dublin District Court on a charge of manslaughter. The student nurse said in evidence that she had been in training for two years but had never previously assisted in the minor operating theatre when a general anaesthetic was being administered. There was no qualified nurse in the theatre at the time. She did not then know of the distinguishing marks on both types of cylinders. She had thought that the cylinders in the rack, about four, were all oxygen cylinders, and had not looked

[1] *British Medical Journal*, August 27, p. 490.
[2] *Irish Times*, September 2, 6, 9, and 20.

at the one she brought into the theatre. A statement made by the house-surgeon showed that she thought the cylinder brought by the nurse contained oxygen, but she did not check it. Other evidence showed that oxygen cylinders used in the minor theatre were black with a white top and were stencilled "O_2" on the neck. Nitrous-oxide cylinders were plain black with a green label bearing the words "nitrous oxide," and both the cylinders in the machine had such a label, though they were not produced in court. Labels and paint were not always in good condition, but the manufacturers repainted the cylinders at least every two years, and often much more frequently. Each type had a differently coloured label and a different serial number. The fittings and valves were identical; in the appliance used in the present case the cylinders were clamped and not screwed into position.

Giving judgment, District Justice Mangan refused to commit the doctor for trial. He found that there had been a default by the doctor, but that the State had not proved that the death had been due to that default. The patient's recent confinement might, as the medical evidence had suggested, have had the effect of raising her blood pressure under the anaesthetic and of leading to a cerebral haemorrhage. The State had not brought evidence of the cause of death, nor even shown that a necropsy had been performed.

Comment

The very full reports in the Irish press do not give any answer to the question why the prosecuting authorities saw fit to arraign this young doctor on a charge of manslaughter. The textbooks show that a much greater degree of negligence is necessary to support a criminal charge than to justify an award of damages in a civil action. The conduct must show such disregard for the life and safety of another as to amount to a crime and deserve punishment. There is no indication in the report that the State adduced any evidence of negligence beyond the mere fact that the accident had occurred, nor was the degree of negligence material to the judgment of acquittal. The prosecutor's omission to lay the groundwork of the case was sufficient to secure that fortunate result. But it is a melancholy reflection that such accidents can still happen after all the fatalities that have already been due to this cause and all the work that the Association of Anaesthetists, the Medical Defence Union, and other bodies have done to prevent them.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

A course of lectures, primarily intended for general practitioners, began on October 12, when Dr. A. M. McFarlan spoke on "Preventing Epidemics: the Doctor's Role." Further lectures in the series, which has been arranged by Professor A. Leslie Banks, Professor of Human Ecology in the University, will be given on the second Wednesday of each month from November, 1949, to July, 1950, at 2.30 p.m., at Addenbrooke's Hospital, Cambridge. Details will be published in the "Societies and Lectures" column of the *Journal*.

UNIVERSITY OF DURHAM

Dr. Arthur Hughes will deliver the sixth Rutherford Morison Lecture on "The Study of the Living Cell" at the Royal Victoria Infirmary, Newcastle-upon-Tyne, on Thursday, November 17, at 5.15 p.m.

UNIVERSITY OF LONDON

Erwin Stengel, M.D., has been appointed to the University Readership in Psychiatry tenable at the Institute of Psychiatry, from October 1.

UNIVERSITY OF WALES

The following candidates for the degrees of M.B., B.Ch. at the Welsh National School of Medicine have satisfied the examiners at the examination indicated:

HYGIENE.—A. G. Alexander, D. F. Brown, Josephine J. Candy, D. E. Copas, B. M. Davies, Ilid M. L. Davies, S. I. Davies, J. M. S. Dixon, J. L. A. Dowse, D. R. T. Evans, J. Evans, B. M. Frost Smith, B. J. Fudge, S. G. Gang, Nansi G. Gwynne, A. R. Harris, A. J. Hooper, Dilwyn T. Jones, Mary E. V. Jones, J. Magell, T. M. Morgan, W. B. Morgan, E. D. Morris, T. L. Morris, G. J. Moses, Margaret Pugh, Dilys Rees, T. A. I. Rees, T. B. Stephens, A. P. Thomas, Margaret E. Thomas, Margaret H. J. Thomas, Anne G. Tighe.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a quarterly meeting of the Council of the College, held on October 13, with the President, Sir Cecil Wakeley, in the chair, a resolution of condolence was passed on the death of Mr. Robert Milne, a past-member of the Court of Examiners.

It was reported that Professor R. V. Bradlaw would deliver the first Webb-Johnson Lecture and that Dr. John Gillies would be the Joseph Clover Lecturer for 1950.

A Diploma of Fellowship was granted to E. J. P. Dennehy.

Diplomas of Membership were granted to R. T. Hughes and O. L. Thomas.

Other diplomas were granted as follows:

FELLOWSHIP IN DENTAL SURGERY.—S. Wilson Charles, R. Fairhurst, G. W. Cathergood, A. R. Thompson, W. F. Collyer, K. P. Liddelow, A. T. Marston, J. W. E. Snawdon, A. M. Norsnell.

FELLOWSHIP OF THE FACULTY OF ANAESTHETISTS.—N. Macdonald, T. Macdonald, R. A. Hingson (Baltimore, U.S.A.), Harry Daly (Sydney, New South Wales).

Diplomas in Tropical Medicine and Hygiene, in Ophthalmic Medicine and Surgery, in Industrial Health, in Child Health, and in Physical Medicine were granted jointly with the Royal College of Physicians of London to the following successful candidates:

DIPLOMA IN TROPICAL MEDICINE AND HYGIENE.—M. el H. Abu Bakr, I. F. Bache, D. N. Banerjee, D. Banerjee, P. H. Birks, S. M. H. Bokhari, S. Chen, Gladys Connor, J. M. Daniel, K. K. Datey, M. M. Desai, J. C. Dutta, H. El Hakim, S. Fazlullah, A. C. Franks, F. C. Harris, J. M. Karim Rehmany, P. W. Kent, S. M. A. Khadri, H. K. Kong, W. S. Kulesza, D. Lawrence, T. Lee, W. S. M. Ling, I. A. McGregor, D. S. McLaren, H. G. McQuade, K. R. Mahajan, A. H. Marsh, A. N. I. Meneces, Deirdre Moore, J. M. Mungavin, C. K. Newman, Gwynfryn A. Owen, W. R. Rochester, A. M. A. Shamy, A. Singh, R. P. Sinha, I. M. S. Stewart, D. E. Thompson, I. G. Thomson, F. G. Williams.

DIPLOMA IN OPHTHALMIC MEDICINE AND SURGERY.—M. M. Ahmad, A. A. Al-Hassany, P. E. Anderson, E. L. Arnold, P. W. Arundell, L. G. Bell, A. Bhattacharya, L. S. Bhave, B. J. Campbell, F. W. Campbell, R. L. Dudhia, G. Forrester, E. Gartside, C. Goldin, J. S. Gourlay, H. J. Harcourt, M. M. Hasan, R. J. A. Heron, R. M. Hewat, K. A. Jabbar, D. B. Jagger, Ruby E. Joseph, W. F. Kinnear, K. Lahiri, S. T. Leong, F.-M. Li, Ethel M. J. Loudon, J. D. McConn, D. G. S. MacPherson, W. G. Merriman, S. S. F. Munro, A. H. O'Malley, R. E. O'Neal, J. V. O'Sullivan, V. Raghavachar, S. R. Robson, S. V. Rush, A. N. Sabbagh, O. W. Salkeld, A. C. Sandston, J. W. R. Sarkies, A. G. Shane, B. S. Sher, G. F. G. Siggins, P. Sivasubramaniam, Marjory B. Snodgrass, M. J. Squires, A. Stafford Steen, A. V. Stevens, K. Vythilingham, A. G. Zalzala.

DIPLOMA IN INDUSTRIAL HEALTH.—L. Banerji, J. J. A. Blakely, C. Crowley, J. J. Das, C. D. Edwards, P. J. Feeny, C. J. Goedvolk, J. Gregory, G. G. Mathews, P. A. B. Raffle, S. K. Raychaudhuri, J. B. L. Tombleson, R. N. E. Watt.

DIPLOMA IN CHILD HEALTH.—C. Abraham, Patience C. Agate, Edith M. M. Alexander, S. U.-D. M. Anabtawi, N. P. Bector, N. R. Butler, W. L. Calnan, J. D. Chalmers, B. E. Cohen, V. B. B. Conaglen, E. G. Cook, Rosemary I. Cook, Jessica B. Core, Flora C. Cowan, J. O. Craig, B. N. Das Gupta, Gwendoline A. M. Donald, W. Edgar, G. V. Feldman, P. M. S. Fischer, Joan Frankton, Patricia Frodsham, W. M. Fyfe, J. M. Garvie, Dora Green, L. Haas, D. C. Henchman, Elisabeth C. W. James, K. E. Jefferson, Barbara Jennings, A. Jervis, A. C. Kendall, Sibyl D. Kiani, G. V. Kinariwala, Grace R. B. Kumarakulasinghe, B. Lake, N. H. Low, R. McDonald, Elizabeth M. Mackie, R. L. Macpherson, Mary R. Menzies, E. H. Minors, E. H. Mirando, M. Mirchandani, Jean Mitchell, Cecil M. Moore, Janet H. Mountford, D. N. Mukherjee, Annie M. Peach, I. C. Peebles, A. F. S. Perera, Maeve Powell, Phyllis Rashbass, Helena M. Reckless, R. V. Rele, Stella M. Ring, E. G. G. Roberts, Marion C. Robinson, A. A. W. Roe, Sheila MacL. Ross, C. M. H. Rotman, R. D. Rowe, R. C. Roxburgh, M. H. Russell, T. R. Savage, Isabel B. Schooling, N. L. Sharma, Margot Shiner, Joan E. T. Spong, J. Steven, A. F. H. Stewart, Victoria W. Symonds, J. J. Tillie, W. M. L. Turner, B. P. Webber, O. H. Wolff, S. Wolff, F. B. M. Woodhouse.

DIPLOMA IN PHYSICAL MEDICINE.—A. R. Brown, W. A. Fell, R. Harris, Ursula E. K. Leitner, A. T. Richardson, B. Shanson, G. R. M. Sutcliffe, J. M. Titcombe, N. M. Vallely.

The following hospitals were recognized under the Fellowship regulations in respect of the resident surgical post required of candidates for the Final Fellowship examination: Amersham General Hospital (resident surgical officer and house-surgeon); Stepping Hill Hospital, Stockport (resident surgical officer and resident assistant surgical officer).

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended October 1. [No. 39

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1949 (a)	(b)	(c)	(d)	(e)	1948 (Corresponding Week) (a)	(b)	(c)	(d)	(e)

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

‖ Includes puerperal fever for England and Wales and Eire.

EPIDEMIOLOGICAL NOTES

Poliomyelitis

Notifications in *England and Wales* for the week ended October 8 were: poliomyelitis 340 (331), polio-encephalitis 34 (26). The figures for the previous week are shown in parentheses. The high prevalence this year is being prolonged beyond the usual time.

The following counties reported multiple cases (poliomyelitis and polio-encephalitis together): London 52 (44), Bedford 5 (5), Berkshire 6 (5), Buckingham 2 (2), Cambridge 3 (0), Chester 5 (4), Cornwall 2 (8), Devon 3 (1), Dorset 7 (5), Durham 2 (3), Essex 31 (26), Gloucester 23 (17), Hertford 4 (12), Kent 26 (19), Lancaster 24 (41), Leicester 4 (2), Lincolnshire, Lindsey 6 (8), Middlesex 30 (18), Norfolk 4 (4), Northampton 4 (4), Northumberland 6 (0), Nottingham 8 (9), Salop 2 (0), Somerset 6 (6), Southampton 4 (7), Suffolk East 4 (2), Surrey 9 (9), Sussex East 2 (5), Warwick 19 (13), Westmorland 2 (0), Wiltshire 4 (8), Yorks East Riding 2 (3), Yorks North Riding 3 (2), Yorks West Riding 50 (38), Glamorgan 7 (6).

Discussion of Table

In *England and Wales* there were increases in the notifications of scarlet fever 208, measles 121, acute pneumonia 87, dysentery 85, and poliomyelitis 63. The only decreases were in the incidence of whooping-cough 105 and diphtheria 16.

The largest increase in the incidence of scarlet fever was 47 in Lancashire. A small increase in the notifications of measles was recorded in most areas; in the north-western counties, however, a fall of 27 was reported.

The largest falls in the notifications of whooping-cough were Warwickshire 39, Yorkshire West Riding 37, and Lancashire 31. A rise was recorded in the incidence of pneumonia in every region except in the south-eastern and south-western counties.

The large rise in the incidence of dysentery was contributed by Lancashire, where 102 cases were notified (Ince in Makerfield U.D. 53, Liverpool C.B. 15, Abram U.D. 10). In London the notifications of dysentery rose from 16 to 24 (Hampstead 18). There was a large incidence of food-poisoning in Lancashire 270 (Liverpool C.B. 257); London 92 (St. Marylebone 67); and Essex 55 (Southend-on-Sea C.B. 20).

In *Scotland* increases were recorded in the notifications of scarlet fever 39 and of acute primary pneumonia 21. The rise in the incidence of scarlet fever occurred in the eastern and western areas. A decrease of 10 in the notifications of dysentery was recorded in Glasgow. An outbreak of paratyphoid B affecting 9 persons was notified in Lanark county.

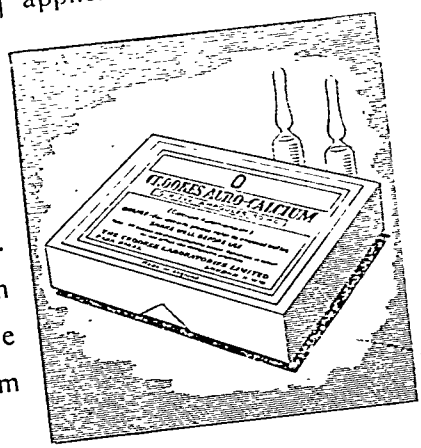
In *Eire* there were increases in the notifications of scarlet fever 23, whooping-cough 23, and measles 26, with a decrease of 16 in the incidence of diarrhoea and enteritis. The rise in the notifications of measles was due to an outbreak of 24 cases in Waterford C.B.

In *Northern Ireland* an increased incidence was reported for whooping-cough 31, scarlet fever 9, and measles 15. The largest increases were: whooping-cough, Belfast C.B. 20; measles, Co. Down 20; scarlet fever, Belfast C.B. 9.

German Statistics

The *Monthly Statistical Bulletin of the Control Commission for Germany (British Element)* is to be discontinued in its present form. The last issue was that for July, which has just been published. Most of its contents will be continued in *Wirtschaft und Statistik* (published by Kohlhammer Verlag, Stuttgart. The articles and reports will be in German only, but a glossary will be appended giving translations into English of table headings, important footnotes, and explanations.

Diphtheria in Scotland



According to an analysis in the October *Health Bulletin* issued by the Department of Health for Scotland, confirmed cases of diphtheria in 1948 numbered 723, and of these 521 occurred in persons who had not been immunized. Deaths in Scotland in 1948 totalled 31, which corresponds to less than 6% of the deaths in 1941. Of the 31 fatal cases, 29 were children who had never been immunized, one was an adult who

GOLD THERAPY in Rheumatoid Arthritis

Controlled studies have shown that chrysotherapy is of definite value and that it is the only treatment which can change the course of the disease in a significant percentage of cases. "It might accomplish in six months or less what nature or general measures might take six years or more to achieve." (*Brit. med. J.*, *1948*,2,755).

Toxic reactions have still to be reckoned with but ". . . because of a reduction in course dosage and the growing use of calcium aurothiomalate, these only occur now in a very small proportion of cases". (*Practitioner*, *1948*,161,156).

AURO-CALCIUM (calcium aurothiomalate) is fully described in the booklet "Crookes Gold Products" (4th edition), obtainable on application.

CROOKES

Auro-Calcium

THE CROOKES LABORATORIES LIMITED · PARK ROYAL · LONDON · N.W.10

When glycogen-laden epithelial cells and Döderlein's bacilli are absent, the pH rises, and pus cells, Trichomonas vaginalis and pathogenic gram-negative bacteria appear.

Acetarsol Vaginal Compound WITH FLAVAZOLE Boots

provides *carbohydrates* and *boric acid* to restore the pH and other conditions favouring the growth of Döderlein's bacilli, *acetarsol*, a tested trichomonacide and *flavazole*, an antiseptic active against both *gram-positive* and *gram-negative* pathogenic bacteria.

Acetarsol Vaginal Compound with Flavazole-Boots

Tablets each containing 4 grains (0.25 G.) of Acetarsol B.P. and 0.2% of Flavazole. Bottles of 25 and 100. *Powder* for insufflation containing 12.5%. of Acetarsol B.P. and 0.2% of Flavazole.

Acetarsol Vaginal Compound-Boots

Tablets each containing 4 grains (0.25 G.) of Acetarsol B.P. Bottles of 25 and 100.

Treatment of exudative dermatoses

Many chronic dermatoses not responding to other methods of treatment over considerable periods respond favourably to 'Siccolam'. There is an immediate reduction in irritation and clinical improvement usually occurs within one or two days.

There are no contra-indications to the use of 'Siccolam' and it may be applied before a final diagnosis has been made without prejudice to subsequent treatment.

had not been immunized, and only one was a child who had been immunized. Half of the children of pre-school age and almost three-quarters of the school-children had been protected by 1948. A decrease in the number of immunizations was recorded in the second half of 1948, the number of inoculations being 38,639, compared with 73,761 in the first half-year and 46,242 in the second half of 1947.

Week Ending October 8

Notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,624, whooping-cough 908, diphtheria 84, measles 926, acute pneumonia 312, cerebro-spinal fever 37, acute poliomyelitis 340, acute polio-encephalitis 34, dysentery 290, paratyphoid fever 18, typhoid fever 18, food-poisoning 121.

Medical News

The R.C.O.G. Dinner

Princess Elizabeth and the Duke of Edinburgh were the principal guests at the dinner of the Royal College of Obstetricians and Gynaecologists held at the Dorchester on October 12, when the president, Sir William Gilliatt, was in the chair. In proposing the toast of the College, the Duke of Edinburgh said he was doing this on behalf of his wife as well as on behalf of himself. The College, he said, had been largely instrumental in reducing infantile and maternal mortality. It was, he said, the first to be "a Commonwealth college." He congratulated the president, Sir William Gilliatt, on looking after its affairs for the last three years: "If he has looked after them in the same capable way that he has looked after my affairs I am not surprised your College has flourished." In response Sir William Gilliatt voiced what was in the mind of everyone in saying that they were proud and delighted that their Royal Highnesses had graced them with their presence. He hoped they felt that the College had made a significant contribution to the community in looking after the welfare of mothers and infants. His fervent hope was that the College would press for the continuous improvement in medical practice of all kinds. Sir William then thanked the officers and all those on the council and committees for their good work. In greeting Professor Hilda Lloyd as his successor he observed that they were the first Royal College to elect a woman as president. Mr. J. A. Stallworthy in a highly felicitous speech proposed the health of the guests. Sir Bennett Hance and Mr. Geoffrey Keynes suitably replied.

Postgraduate Travelling Fellowships

The British Postgraduate Medical Federation (University of London) is offering a limited number of travelling fellowships, tenable for one year, to registered medical practitioners who are training as specialists in one of the preclinical or clinical branches of medicine or surgery at one of the medical schools or teaching hospitals of the University of London. *Further information about these fellowships will be found in* the advertisement columns at p. 34.

Chelsea Clinical Society

The first dinner meeting of the fifty-third session was held on October 11 at the South Kensington Hotel, with the president, Dr. Maurice Bewley, in the chair. An interesting discussion on hormones was opened by Dr. P. M. F. Bishop and continued by Dr. Raymond Greene.

Road Accidents

Discussing physical disabilities and alcoholism in relation to road accidents at the Congress of the Royal Society for the Prevention of Accidents on October 5, Dr. J. A. Gorsky said that the field was comparatively unexplored. There was an urgent need for further investigation into the problems of visual defects and accident proneness as causative factors in road accidents. The danger of alcohol to drivers was becoming recognized and appreciated by the responsible majority of motorists, but more needed to be done by way of propaganda and public relations. He was astonished that in the case of fatal road accidents the Ministry of Transport did not adopt the same procedure as the Ministry of Labour, which sends one of its factory inspectors to attend the coroner's inquest when there has been a fatal industrial accident. It might be necessary to make tests for driving licences more stringent. That would mean a sacrifice of freedom. Most people who thought clearly about the problem had recognized the point, but it meant an enormous change of attitude and outlook.

History of War

The lines on which the official medical histories of the last war are being prepared were described in the *Medical Journal of Australia* of June 18 (p. 818) by Mr. W. F. Mellor, secretary of the United Kingdom Official Medical History of the War. In Britain as early as March, 1941, an editorial board was set up under the chairmanship of the Rt. Hon. R. A. Butler, M.P., then President of the Board of Education, with Sir Arthur MacNalty as Editor-in-Chief. The board first met in July of the same year. Subsequently Sir Cyril Flower, Deputy Keeper of the Public Records, succeeded to the chair of the board. Similar work was started in the Commonwealth and the U.S.A. The medical history will be divided into three main sections: (1) Evolution and development of the administrative services to meet war conditions; (2) the medical aspects of the campaigns; and (3) the advances in clinical medicine and surgery. There will also be sections on medical research and statistics. A number of the histories were already in preparation when the war ended in 1945. A conference of Commonwealth medical historians to study the possibilities of collaboration was therefore held in London in January, 1946, and as a result a liaison committee was established. This committee last met at Canberra on October 3–8 and discussed in particular the campaign in the Near and Far East, as well as the progress made in those theatres in the prevention and treatment of tropical diseases.

Memorial to Dr. John Snow

A tablet commemorating Dr. John Snow's residence at 18, Sackville Street, London, W.1, was affixed to this house on October 18. The tablet is inscribed "John Snow (1813–1858), physician and specialist anaesthetist, who discovered that cholera is water-borne, lived here." It was John Snow who administered chloroform to H.M. Queen Victoria on April 7, 1853, at the birth of the Prince Leopold. His work on cholera overshadowed his fame as a pioneer anaesthetist

Exploring Norway

The British Schools Exploring Society is arranging an expedition to Northern Norway from August 2 to September 15, 1950, and invites applications for the posts of honorary physician and honorary surgeon. The cost to each member of the party will be £110, plus £12 for personal equipment. Applicants should write as soon as possible to the assistant secretary of the society, c/o Royal Empire Society, Northumberland Avenue, London, W.C.2, suggesting a day when they could come to London for an interview.

Princess Tsahai Memorial Hospital

A bazaar will be held at the Kingsway Hall, London, W.C.2, on December 1 from 3 p.m. to 7 p.m. and on December 2 from 11 a.m. in aid of the Princess Tsahai Memorial Hospital. Funds are still urgently needed to complete the hospital, and cheques and postal orders will be gratefully received by the honorary treasurers, Lord Horder and Lord Amulree, c/o Messrs. Gould and Prideaux, 88, Bishopsgate, London, E.C.2. Gifts for the bazaar and offers to help should be sent to the honorary secretary, Miss E. Sylvia Pankhurst, 3, Charteris Road, Woodford, Essex.

Carnegie United Kingdom Trust

Mr. J. Murray Black, surgeon to Dunfermline and West Fife Hospital, was elected a life trustee of the Carnegie United Kingdom Trust in March this year.

Milk Foods

Proprietary infant milk foods and National Dried Milk are now available as an alternative to liquid milk for children up to 2 years of age instead of 1 year. Anyone wanting to obtain permission to buy these preparations for a child between the ages of 1 and 2 should take or send the child's ration book to the local food office.

COMING EVENTS

Honyman Gillespie Lectures

A series of Honyman Gillespie Lectures has been arranged in association with the Edinburgh postgraduate courses to take place during the autumn term in the anatomy theatre, University New Buildings, Teviot Place, Edinburgh, on Thursdays, at 5 p.m. The first lecture on "Regional Ileitis" was delivered by Mr. James S. Jeffrey on October 20, and the series will end on December 1. Details will be published under "Societies and Lectures" in the *Journal* week by week. The lectures are open to all graduates and senior students.

Torquay Medical Society

The following lectures will be given at the meetings of the Torquay and District Medical Society at Torbay Hospital: "Common Gynaecological Lesions and their Diagnosis," by Mr. H. J. Drew Smythe, October 27 at 8.30 p.m.; "Headache," by Dr. Anthony Feiling, November 24 at 8.30 p.m.; "The Coroner and the Modern Medical Profession," by Mr. Bentley Purchase, January 12, 1950, at 8.30 p.m.; "Modern Clinical Endocrinology," by Dr. S. L. Simpson, February 9, 1950, at 8.30 p.m.; "Some Recent Advances in Paediatrics" by Dr. Wilfred Sheldon, March 9, 1950, at 8.30 p.m.; and "Diseases of the Rectum and Anus and their Treatment," by Mr. R. Marnham, March 23, 1950, at 8.30 p.m.

University College Hospital Medical School

The annual dinner of past and present students (men and women) of University College Hospital Medical School will be held at Savoy Hotel, Strand, W.C., on Friday, October 28, at 7.30 for 8 p.m., when the chair will be taken by Mr. John B. Hunter. Applications for tickets (£1 7s. 6d. each), accompanied by remittance, should be made to the dinner secretary, University College Hospital Medical School, University Street, London, W.C.1. On Thursday and Friday, October 27 and 28, there will be lectures and demonstrations for old students at the medical school from 10.30 a.m. to 5 p.m., and on Friday, October 28, at 5 p.m. the annual general meeting of the Old Students' Club will be held in the Medical Society's rooms in the Medical School.

Royal Dental Hospital of London

A dinner of past and present students of the Royal Dental Hospital of London will be held at the Savoy Hotel, London, W.C., on Saturday, October 29, at 7 for 7.30 p.m., when Professor E. C. Sprawson will preside. The annual clinical "At Home" will be held at the hospital, 32, Leicester Square, W.C., at 3 p.m. the same day, when cases of clinical interest illustrating the scope of the work undertaken by the hospital will be shown and the various departments of the hospital and school will be open for inspection. At 12.30 p.m. Dr. Lilian Lindsay will formally open the Stobie Memorial Library.

Organic Nervous Disease

The Committee on the Welfare of the Disabled of the Scottish Council of Social Service has arranged for a conference to be held on "The Disability of Organic Nervous Disease" at the Lesser City Hall, Perth, on November 4–5. There will be delegates representing the education, health, and welfare committees of local authorities and of voluntary organizations. The speakers include Dr. G. W. Ireland, on "The Problems of Nervous Disease from the Point of View of a General Practitioner"; Dr. John B. Gaylor, on "The Nature of Epilepsy"; Dr. J. Romanes Davidson, on "The Function of the Epileptic Colony"; and Mr. Joseph Schorstein, on "Head Injuries." Further information may be obtained from the Scottish Council of Social Service, 10, Alva Street, Edinburgh.

Lighting in Hospitals

A paper on "Specialized and General Lighting in Hospitals" by Mr. M. W. Pierce and Mr. D. J. Reed will be read at a meeting of the Illuminating Engineering Society on November 8 at 6 p.m. The meeting starts at 5.15 p.m. and will be held at the Lighting Service Bureau, 2, Savoy Hill, London, W.C.2. Particulars may be obtained from the society at 32, Victoria Street, London, S.W.1.

SOCIETIES AND LECTURES

Friday

BRITISH INSTITUTE OF RADIOLOGY.—At Reid-Knox Hall, 32, Welbeck Street, London, W., October 21, 5 p.m., Meeting of medical members; 6.30 p.m., "*Standardization of Radioactive Isotopes*." Speakers: L. H. Gray, Ph.D., J. L. Putman, M.A., and W. K. Sinclair, M.Sc.

MAIDA VALE HOSPITAL FOR NERVOUS DISEASES MEDICAL SCHOOL. Maida Vale, London, W.—October 21, 5 p.m., clinical demonstration by Dr. A. Feiling.

MEDICAL WOMEN'S FEDERATION.—At City Hall, Cardiff, October 21, 3 p.m., annual general meeting; 8.30 p.m., at National Museum of Wales, reception by Cardiff Division of B.M.A.

MIDDLESEX COUNTY MEDICAL SOCIETY.—At Hillingdon Hospital Uxbridge, October 21, 3 p.m., demonstration of radiographs and pathological specimens; 3.15 p.m., business meeting, followed by paper on "*Respiratory Patterns during Surgery and Anaesthesia*," by Dr. H. J. V. Morton; 5 p.m., "*Diagnosis in Cases of Jaundice*," by Dr. A. R. Harrison. A discussion will follow each paper.

Monday

MEDICAL SOCIETY OF LONDON, 11, Chandos Street, Cavendish Square, London, W.—October 24, 8.30 p.m., Discussion: "*Deafness*," to be introduced by Messrs. T. E. Cawthorne and I. G. Robin.

UNIVERSITY COLLEGE, Gower Street, London, W.C.—October 24, 4.45 p.m., "*Technique and Applications of Tissue Culture*," by Dr. Charity Waymouth.

Tuesday

BARROW AND FURNESS CLINICAL SOCIETY.—At Orthopaedic Clinic, North Lonsdale Hospital, October 25, 8 p.m., first meeting of season.

BRISTOL UNIVERSITY.—At Large Physics Lecture Theatre (Royal Fort), October 25, 8.15 p.m., "*The Use of Tracer Elements in Biology and Medicine*," 38th Long Fox Memorial Lecture by Professor J. E. Harris.

EDINBURGH POSTGRADUATE BOARD FOR MEDICINE.—At University New Buildings (Anatomy Lecture Theatre), Edinburgh, October 25, 5 p.m., "*New Orientations in Epilepsy*," by Dr. Denis J. Williams.

EUGENICS SOCIETY.—At 26, Portland Place, London, W., October 25, 5 p.m., "*Intelligence and Fertility: An Investigation of Scottish Children*," by Sir Godfrey Thomson, D.C.L., Ph.D., D.Sc. All interested are invited to attend.

INSTITUTE OF DERMATOLOGY, 5, Lisle Street, Leicester Square, London, W.C.—October 25, 5 p.m., "*Histopathology of the Skin*," by Dr. I. Muende.

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Postgraduate Medical School of London, Ducane Road, W., October 25, (1) 2 p.m., "*The Problems of Mammary Carcinoma in Pregnancy*," by Mr. A. Lawrence Abel; (2) 3 p.m., "*Anaemia in Pregnancy*," by Professor L. S. P. Davidson.

LONDON UNIVERSITY.—At St. Mary's Hospital Medical School, Norfolk Place, Paddington, London, W., October 25, 5 p.m., "*Recent Studies in the Physiology and Pharmacology of the Cerebral Circulation*," by Professor C. F. Schmidt (University of Pennsylvania).

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—October 25, 5 p.m., "*The Development of the Mammary Gland*," Arris and Gale Lecture by Mr. E. S. R. Hughes.

Wednesday

GLASGOW UNIVERSITY: DEPARTMENT OF OPHTHALMOLOGY.—October 26, 8 p.m., "*Gyrate Atrophy of the Choroid*," by Dr. A. Wright Thomson.

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Chelsea Hospital for Women, Dovehouse Street, London, S.W., October 26, (1) 11 a.m., "*Vaginal Hysterectomy, Indications and Technique*," by Mr. C. M. Gwillim; (2) 12 noon, "*Oestrogens*," by Professor E. C. Dodds, F.R.S.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Portland Place, London, W.—October 26, 3.30 p.m., "*Some Popular Fallacies Regarding Human Nutrition*," by Dr. H. E. Magee.

ROYAL SANITARY INSTITUTE, 90, Buckingham Palace Road, London, S.W.—October 26, 2.30 p.m., "*The Common Cold*," discussion to be opened by Dr. W. H. Bradley (Ministry of Health).

SOCIAL PSYCHOTHERAPY CENTRE, 7, Fellows Road, London, N.W.—October 26, 5 p.m., "*The History of Social Psychiatry and Group Psychotherapy and the Principles of Social Psychiatry*," by Dr. Joshua Bierer.

SOCIETY OF CHEMICAL INDUSTRY.—Joint meeting of Nutrition Panel and Agriculture Group at Chemical Society's rooms, Burlington House, Piccadilly, London, W., October 26, 6.15 p.m., "*Genetic Factors Affecting the Nutritional Value of Animal Products*," by Dr. J. Hammond; "*Genetic Factors Affecting the Nutritional Value of Crops*," by Mr. R. H. Richens.

Thursday

HONYMAN GILLESPIE LECTURE.—At Anatomy Theatre, University New Buildings, Teviot Place, Edinburgh, October 27, 5 p.m., "*Diastole*," by Dr. Bruce Williamson.

INSTITUTE OF UROLOGY.—At Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C., October 27, 5 p.m., "*Bone Syphilis*," by Mr. A. E. W. McLachlan.

MEDICO-LEGAL SOCIETY.—At 26, Portland Place, London, W., October 27, 8.15 p.m., "*The Use of Scientific Research in Medico-legal Practice*," Presidential address by Dame Louise McIlroy.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Corner, London, S.W.—October 27, 4.30 p.m., lecture-demonstration: "*Psychiatry*," by Dr. D. Curran

TORQUAY AND DISTRICT MEDICAL SOCIETY.—At Torbay Hospital, October 27, 8.30 p.m., "*Common Gynaecological Lesions and their Diagnosis*," by Mr. H. J. Drew Smythe.

Friday

KENT AND CANTERBURY HOSPITAL, Canterbury.—October 28, 8 p.m., clinical meeting.

LONDON UNIVERSITY.—At Westminster Medical School (Meyerstein Lecture Theatre), Horseferry Road, London, S.W., October 28, 5.30 p.m., "*The Indispensability of Biologically Labile Methyl Groups in the Diet and Transmethylation*," by Professor V. du Vigneaud (Cornell University Medical College).

MAIDA VALE HOSPITAL FOR NERVOUS DISEASES MEDICAL SCHOOL, Maida Vale, London, W.—October 28, 5 p.m., clinical demonstration by Dr. S. Nevin.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES, 11, Chandos Street, London, W.—October 28, 8 p.m., "*Is Treatment Before Diagnosis on Suspicion of Venereal Disease Advantageous to (a) the Patient, (b) the Public Health?*" discussion to be opened by Colonel L. W. Harrison.

ROYAL INSTITUTE OF PHILOSOPHY, 14, Gordon Square, London, W.C.—October 28, 5.15 p.m., "*Russell's Neutral Monism*," by Professor H. H. Price,

ROYAL MEDICAL SOCIETY, 7, Melbourne Place, Edinburgh.—October 28, 8 p.m., "*The Dawn of Tropical Medicine (The Life and Work of Sir Patrick Manson)*," by Sir Philip Manson-Bahr.

UNIVERSITY COLLEGE, Gower Street, London, W.C.—October 28, 5.15 p.m., "*Transmission of Excitation in Nerve and Muscle*," by Dr. Bernhard Katz.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

John.—On October 6, 1949, at 2, Chessel Avenue, Southampton, to Gene (née Sinton) and Dr. Alan Oakley John, a sister for Marilyn and Elisabeth—Alison Ruth.

Kerr.—On October 9, 1949, at Aylesbury, to Mary (née Talbot), wife of J. G. Kerr, M.Ch.(Orth.), a son.

MARRIAGES

Critchley—Watson.—On October 1, 1949, at St. Paul's Church, Birkenshaw, Yorks, James Michael Allis Critchley, M.B., Ch.B., to Isobel Vernon Watson, M.B., Ch.B.

Davies—Stuart.—On September 13, 1949, at Blackfriars Church, Glasgow, David M. Davies, M.B., B.Ch., to Marie Stuart.

DEATHS

Inglis.—On October 12, 1949, at Falkirk Royal Infirmary, James Charles Inglis, M.B., Ch.B.

James.—On October 13, 1949, at the National Hospital, Queen Square, London, W.C., Richard Gostwycke James, O.B.E., M.R.C.S., L.R.C.P., of Kingham, Norwich, Norfolk.

Kaye.—On October 2, 1949, at Boscombe Hospital, Ernest George Kaye M.B., B.S., of 40 Princess Road, Bournemouth West, aged 76

Kyle.—On October 8, 1949, at St. George's Hospital, James Kyle, M.R.C.S., L.R.C.P., Air Commodore, R.A.F. Medical Branch, Ret., of Brendon, Wendover, Bucks.

La Frenais.—On October 2, 1949, Joseph Everett La Frenais, L.R.C.P.&S.Ed., L.R.F.P.S., of Tower House, Runcorn, Cheshire.

Lanyon.—On October 4, 1949, at Penzance, Edgar Temple Lanyon, M.R.C.S., L.R.C.P., of 49, Udet Road, Liverpool.

Lewis.—On October 3, 1949, suddenly, at Great Ormond Street, London, W.C., Jonathan Nicholas Lewis, aged 1 year 6 months, very dear son of Drs. Charles and Evelyn Lewis, of 28, Michelham Gardens, Twickenham, Middlesex.

MacInnes.—On October 9, 1949, at Cairn Villa, Broadford, Skye, Alexander MacInnes, M.B., Ch.B.

Masson.—On October 14, 1949, at 33, Kaimes Road, Corstorphine, Edinburgh, James Masson, M.B., Ch.B., F.R.C.S.Ed., Lieutenant-Colonel I.M.S., Ret.

Milne.—On September 29, 1949, at Aldeburgh, Suffolk, Robert Milne, M.S., F.R.C.S., Surgeon Rear-Admiral R.N., of 75, Portland Place, London, W.

Raban.—On October 2, 1949, at Bristol General Hospital, John Pridmore Raban, M.R.C.S., L.R.C.P., D.M.R.E.

Wilkes.—On October 8, 1949, at Folkestone, Ernest Alfred Freear Wilkes, M.R.C.S., L.R.C.P., D.P.H., of 2, Clare Lawn Avenue, East Sheen, London, S.W.

Wilson.—On October 6, 1949, at 35, Park Place, Elie, Fife, John Johnstone Wilson, M.D., F.R.C.P.Ed., formerly of Anstruther, Fife, aged 81.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Copra Bug

Q.—*From time to time I am called upon to treat dockers suffering from alleged bites by an insect known as the "copra bug," which infests cargoes of copra. I should be glad of information about the nature of this insect, and of advice about prophylactic measures. The best solution would be treatment of the cargo with an insecticide which would not impair the edibility of the oil subsequently expressed from the copra, but, failing this, is there any local application which could be used on the dockers' skin?*

A.—The "copra bug" is a species of mite. *Tyrophagus castellani*. This mite occurs fairly commonly among stored food with a relatively high fat and protein content, such as linseed, dried egg, nuts, cheese, herring meal, and copra. Skin irritation is caused to people handling infested foodstuffs, possibly by the excretory products as well as by the mites themselves, for material containing large numbers of dead mites is said to cause the same symptoms. The easiest way to deal with complaints of irritation from this mite is to introduce a repellent to be rubbed on the skin of persons coming in contact with it. Undiluted dimethyl phthalate can be used, or a preparation containing 30 to 40% of it; several such preparations are available. A small quantity of the repellent should be rubbed over the skin of the hands, arms, etc., of the workmen each morning.

Cancer of Cervix Uteri

Q.—*Is it ever necessary or advisable to repeat treatment with radium for cancer of the cervix? A woman of 36, a multipara, with a carcinoma proved at biopsy, has been given three radium exposures of 1,800, 2,000, and 1,875 units (total 5,675 units) followed by 12 deep x-ray irradiations at one to two days' intervals. The bleeding stopped after the first exposure to radium. Severe excruciating pain radiating down the left thigh and the coccygeal region occurred after the second radium exposure and persisted till a month ago, when an ulcer covered by offensive slough was detected at the site of the cancer. The surrounding area was hard and tender. A course of penicillin injections was then started, and this relieved the pain. Every evening there is tingling or mild pain in the lower abdomen or left thigh. The ulcer is clean but not healed, and the surrounding area is somewhat hard. Local penicillin ointment is being continued. There is no glandular enlargement or metastasis. Could you advise me on the next steps to be taken? What is the latest treatment of this type of cancer?*

A.—This question is in three parts. The first is a general question on the need for or advisability of repeated treatment with radium for cancer of the cervix. Only in a very few cases of cancer of the cervix specially selected on their merits would irradiation with radium be justifiable. In general, subsequent irradiation of the cervix following a full course of irradiation by radium or by radium and *x* rays will do nothing but harm.

The second part of the question is concerned with an individual patient. The information given does not include details of the time between the radium exposures or the size, arrangement, or dosage of the *x*-ray fields or the quality of the *x*-ray radiation used. If the treatment was of the type frequently used, it would seem that the initial course was reasonably adequate or even possibly a little excessive. It appears likely that there is some infection in the left pelvis, the situation of the pain suggesting that this might have been in a lymph node in the pelvic wall. The presence of an ulcer at the site of the cancer does not necessarily indicate a recurrence; this might be a radio-necrotic ulcer to which infection could have

been a contributory cause. It would be advisable to make sure that the ulcer is free from Gram-negative organisms before using penicillin ointment. In spite of the absence on examination of evidence of glandular enlargement or metastasis, the pain of which the patient complains suggests some irritation of the upper lumbar nerve distribution on the left side. As regards treatment, the following is suggested. Biopsy of the ulcer should be performed and local treatment with sulphonamides and penicillin continued. If the ulcer is malignant, hysterectomy should be carried out if possible, at which the glands can be inspected and localized; these might subsequently be irradiated. A Wertheim hysterectomy in skilled hands would be preferable. If hysterectomy is contraindicated, then local treatment by diathermy coagulation should be given, followed by local removal of the cervix if healing does not seem to be well advanced in two months. If the ulcer is benign, local treatment with sulphonamides and penicillin supplemented by hypertonic saline douches should be continued. Coagulation diathermy of the ulcer could be tried, but not until at least three months have elapsed.

To the third part of the question—What is the latest treatment for this type of cancer?—the answer is, Very extensive surgery, according to the clinical stage, or radium and *x*-ray treatment combined; though different practitioners would probably give different answers. The best published results are from the Marie Curie Hospital, London, and the Fondation Curie Hospital, Paris, both radiotherapeutic institutions.

Suspected Food-poisoning

Q.—*During the summer there have been numerous isolated attacks of sickness and diarrhoea which have cleared up in a few days with simple treatment. These attacks are probably due to something the patients have eaten. Should these cases be notified and, if so, under what heading?*

A.—If it is suspected that cases of sickness and diarrhoea are due to food inherently non-poisonous but to which has been added, or in which has developed, a toxic substance (chemical or bacterial) or a growth of pathogenic bacteria, such cases should be notified as food-poisoning under Section 17 of the Food and Drugs Act, 1938. The main purpose of this section of the Act is to ensure that the local medical officer of health is informed of outbreaks of illness occurring in his district and believed to have been caused by food. The Act did not give any definition of the term "food-poisoning," but the matter is dealt with in the Ministry of Health Memorandum on Food Poisoning, No. 188/Med. (revised 1949), from which it is clear that cases in which food causes an infectious disease otherwise statutorily notifiable as such—for example, typhoid fever, scarlet fever, and dysentery—should not be notified as food-poisoning. It is evident, however, that there would be no reflection on a doctor who, on clinical grounds, notifies as food-poisoning a case in which the final diagnosis after investigation proves to be dysentery. The medical officer of health can, with the consent of the doctor concerned, correct such provisional notifications in the quarterly return made to the Registrar-General. Illness due to individual idiosyncrasy to certain foods—that is, to allergy or hypersensitivity—and to the consumption of foods inherently poisonous—for example, toxic fungi mistaken for mushrooms—should not be notified as food-poisoning.

Interpretation of Dreams

Q.—*Can you explain why the manifest dream is sometimes, if not always, so fantastically different from the thoughts or feelings which have given rise to it? I was woken by such a dream last night. Associations came easily and soon the underlying causes seemed clear. But for a long time I lay awake wondering why it had been necessary to wrap them up so elaborately.*

A.—There are several theories of the interpretation of dreams, but in the writer's opinion the dream is always the product of an unresolved problem, which, because we cannot solve it, we repress so that it becomes unconscious (which, indeed, is the next best thing to do if we cannot solve it, so that we may get on with the business of life). But the problem nevertheless remains, and refuses to be repressed, being insistent that its claims should be attended to. Therefore what we refuse to acknowledge in waking life emerges as a dream, which forces us to face a problem we are refusing to face. But also because we refuse to allow the problem in consciousness it must appear in disguised forms. Sometimes it does this by symbols which are less direct than the unpleasant facts themselves. Sometimes we draw upon earlier experiences of the same nature, having the same emotion, exemplifying the same type of experience, or illustrative of the same problem. So bits of past experiences, apparently irrelevant and illogical, but always associated with the problem, appear in the dreams. In other cases the problem is put in a more acceptable light, such as when feelings of rage appear as righteous indignation, or feelings of humiliation are transformed into humiliating others. Indeed, it does not seem to matter a great deal how the problem or emotion comes out so long as it is released and the unpleasant problem is brought to mind. Freud has dealt with many of the causes of such "dream distortion" in his *Interpretation of Dreams*.

In brief, distortion is due to our refusal to face the problem as such, so that other relevant material illustrative of the problem or in some way associated with it is drawn upon to serve the purpose of forcing its attention on a reluctant mind for solution. It is all these symbols, scraps of experiences, transformations, and substitutions which give to the dream its bizarre nature; and it is only by investigating each item that we can fit them, like a jigsaw, into a reasonable pattern.

NOTES AND COMMENTS

Antiseptics for Minor Dressings.—Mr. John Roberts (Bangor, Caernarvonshire) writes: I would like to support Dr. Rupert Palmer (October 1, p. 768) in his spirited defence of mercury perchloride. Without doubt it is one of our most valuable, efficient, and inexpensive antiseptics, with the great advantage of being lethal to the majority of pathogenic organisms, which cannot be claimed for some of the modern and selective biochemical products. There are theoretical disadvantages to this chemical in that it is highly toxic parenterally and it coagulates tissue albumins, etc., but these objections come from laboratory workers and others out of touch with daily clinical work in which the drug is used as a surface application. It may be that it has come under suspicion because of occasional harmful results from mercurial diuretics or from occasional cases of chronic poisoning in pink disease and in finger-print workers using the material habitually, but this is no reason for condemning such a useful and potent antiseptic.

A 1 in 4,000 solution of mercury perchloride in warm water is invaluable as an irrigating lotion in cases of middle-ear suppuration, and if the tympanic membrane is intact a 1 in 2,000 solution can safely and most efficiently be used for external otitis (including the fungoid infections). I have used the weaker solution with much success for washing out the odd case of persistently dirty maxillary antrum (a few with gross fungus infection), but only through an antrostomy opening. Idiosyncrasy has been extremely rare in my experience, and this is in agreement with Dr. Palmer's remarks.

For surgery or hospital use mercury perchloride is available in the small, readily soluble 1.75-gr. (50-mg.) tablet, coloured blue, and one of these dissolved in 4 oz. (114 ml.) of water gives a 1 in 1,000 solution. One tablet in 16 oz. (454 ml.) of warm water is correct for middle-ear suppuration. These tablets are of course intensely poisonous by mouth, and the 1 in 1,000 solution (coloured blue) for appropriate dilution should be used for dispensing, with all due precautions. I am aware of the claims of the new organic mercurials (phenyl mercuric acetate, nitrate, chloride, etc.), but so far I have been quite satisfied with the older chemical.

All communications with regard to editorial business should be addressed to The Editor, British Medical Journal, B.M.A. House, Tavistock Square, London, W.C.1. Telephone: Euston 2111. Telegrams: *Aitiology, Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.) Telephone: Euston 2111. Telegrams: *Britmedads, Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the Secretary of the Association. Telephone: Euston 2111. Telegrams: *Medisecra, Westcent, London.*

B.M.A. Scottish Office: 7, Drumsheugh Gardens, Edinburgh.

SUPPLEMENT TO THE
BRITISH MEDICAL JOURNAL
LONDON SATURDAY OCTOBER 22 1949

WORLD MEDICAL ASSOCIATION

GENERAL ASSEMBLY IN LONDON

International Standards of Medical Practice

The national medical associations of 28 countries were represented by twice that number of delegates at the third annual assembly of the World Medical Association, which was held at B.M.A. House, London, from October 11 to 15. In addition to the delegates the meeting was attended by observers from WHO, Unesco, ILO, the World Federation for Mental Health, and various international medical organizations. Observers were also attached to several of the delegations, and 30 members of the United States Committee—the supporting organization of the WMA in America—were present in the same capacity.

The following are the countries from which the delegates came: Australia, Austria, Belgium, Canada, Colombia, Cuba, Denmark, Eire, Finland, France, Great Britain, Greece, Iceland, India, Italy, Luxembourg, Netherlands, Norway, Pakistan, Peru, Philippines, Portugal, South Africa, Spain, Sweden, Switzerland, Turkey, United States of America.

The delegates from the British Medical Association were Dr. H. Guy Dain and Dr. J. A. Pridham, with Dr. E. A. Gregg and Dr. S. Wand as alternates. Dr. John Yui, of the Chinese Medical Association, was not able to attend, but he sent a cablegram of greeting, and the assembly was continually reminded of its Far Eastern affiliation by the Chinese temple gong—a gift by Dr. Yui at a previous meeting—with which the president kept the delegates in order. The languages spoken were English and French, with occasional Spanish. Dr. Gérin-Lajoie, of Canada, rendered excellent service as an interpreter.

Election of Dr. Charles Hill as President

The assembly opened on the morning of October 11 with a welcome to the delegates by the outgoing President, Professor Eugène Marquis (France), who referred to two large pieces of work which the Association had already accomplished—its declaration on the punishment of war crimes by medical men, and the Declaration of Geneva, a modern version of the Hippocratic Oath. He then moved confirmation of the election of Dr. Charles Hill as President, saying that in all countries they knew enough of Dr. Hill's quality to be sure that under his guidance the Association would make great progress.

The election having been unanimously confirmed, Dr. Hill took the chair, and, after expressing his sense of the honour done to him, proceeded to thank Professor Marquis in the name of the assembly for his outstanding services as first President of the Association. The Chairman of Council (Dr. T. C. Routley) and Dr. Dag Knutson (Sweden) spoke in similar terms, and the former asked the President to present to Professor Marquis in token of his term as President a suitably inscribed gavel; and this was done, the delegates standing and applauding.

Certain formal business was then taken, including the admission to membership of two national medical associations which had qualified under the articles—namely, the Asociacion Medica Nacional of Panama and the Colegio Medico of Salvador.

The Finance of the Association

Dr. O. Leuch, the Treasurer, presented the accounts for the past year and the budget for 1949–50. He said that the Council had decided that for the coming year the annual subscription for countries in the sterling area should remain at the same amount as for 1948–9. National associations in the sterling area, if their membership had not increased, would pay no more than before, notwithstanding the devaluation of their currencies. The whole matter would be reconsidered next year. Dr. L. L. Davey (Australia) expressed appreciation of this decision.

Dr. L. H. Bauer (Secretary-General) brought forward the annual budget of the United States Committee. He recalled that at the meeting in Paris in 1947 the U.S. delegation had offered to subscribe 50,000 dollars a year for five years to get the Association on its feet financially. That was accepted, and in 1948, although the committee was operating only for nine months of that year, the amount actually expended was 59,481 dollars, and for the first half of 1949 29,484 dollars. For 1950 the tentative budget was 75,700 dollars.

The committee had been established as a non-profit organization. The American Medical Association, in addition to its annual subscription to the WMA, was a contributing member of the U.S. Committee, as were other medical organizations in the States, as well as certain well-recognized pharmaceutical houses. An effort had been made to interest individual doctors in the matter by proposing a subscription of 10 dollars a year, and this year 12,000 dollars had been subscribed by individual doctors.

Dr. Leuch moved a vote of thanks to the U.S. Committee, and especially to the leaders of the American Medical Association who had created it. The motion was supported by Dr. Knutson, who said that most doctors did not know what was going on outside their own association, and the American example should be copied in every country.

Report of the Council

Dr. Routley, in presenting the report of the Council, said that three meetings had been held—in Geneva, in Madrid, and in London. The report dealt with a number of matters, but he wished to make it clear that it was the view of the Council that the Association should not attempt to propose to any member-country how it should conduct its affairs; its function was to make known to all countries the information which reached it and to endeavour so far as possible to maintain international standards of medical practice.

Dr. Routley went on to indicate certain proposals, all of which were adopted, for the future programme of the Association. The first was a proposed conference for the co-ordination of scientific medical organizations. He said that the Council was not unmindful of the activites of Unesco in this field, and had no desire to overlap, but what they had in mind was something beyond the scope of Unesco activities. The Council also proposed to make a study of pharmaceutical practices, including the newer therapeutic agents (the sulphonamides, penicillin, streptomycin, etc.), the extent to which these agents were available in different countries, any government subsidies affecting their distribution, and any restrictions on prescribing these agents, either in private practice or in social security schemes.

A further study proposed concerned hospitals, their types (government, private teaching, etc.) in each country, the number of hospital beds in relation to the population, the availability of hospital facilities, and the control and financial support of hospitals.

Further, a study of the status of the medical profession, especially in relation to medical man-power and membership of the national associations in the different countries, was proposed. This would be supplementary to a study which the Association had already published, concerning 23 countries, dealing with medical man-power and other subjects.

Dr. O. Rasmussen (Denmark) asked whether it would not be wise to include in this last study an examination of the economic position of doctors in different countries in relation to that of other professions. Dr. Routley said that this suggestion had much merit, and unless there were objections which did not occur to him at the moment he would agree on behalf of the Council that this study should include the wider field of economic relationships.

The reports and proposals of the Council were all accepted by the assembly, and Dr. Routley concluded by expressing appreciation of the help afforded by the Assistant Secretaries for Asia, Australasia, Europe, and Latin America respectively; by the editor of the *Bulletin*, Dr. Morris Fishbein, and his collaborating editors, and by the observers on intergovernmental organizations, such as the WHO. The WMA must be to WHO, he said, what electric power was to the transmission line.

The assembly adopted an emblem—a globe, with the rod of Aesculapius placed diagonally across it, and around the border the words "Societas Medicorum Mundi. MCMXLVII A.D.".

Reports from the Continents

Three of the Assistant Secretaries—the fourth, Dr. J. G. Hunter for Australasia, has only recently been appointed and was not present—gave brief reports. Dr. S. C. Sen, for Asia, said that of 16 countries in his region four were represented in the WMA. In India at the present moment the problems engaging the attention of the Government and the medical profession concerned the recognition, status, and educational standard of the indigenous systems of medicine, known as Ayurveda, Unani, etc., a scheme in connexion with the Employees Insurance Act, and the establishment of new medical colleges and upgrading of departments in colleges with a view to providing facilities for research and post-graduate education.

Dr. Paul Cibrie, Assistant Secretary for Europe, reported that it had been impossible to correspond with three countries which originally adhered to the Association—Poland, Czechoslovakia, and Rumania. An inquiry was being made into the activities of the Red Cross in time of peace; it appeared that in some European countries certain activities of the Red Cross invaded the sphere of general medical practice. The outstanding event of the year in Europe was the inauguration of the National Health Service in Great Britain, but that, if it came before the WMA at all, would properly be introduced by the British delegates.

Dr. J. A. Bustamante, for Latin America, described the activities of the Pan-American Medical Confederation, which ran parallel in Latin America with those of the WMA. Dr. Bustamante himself was secretary-general of the Confederation, so that the liaison could not be closer. Chile, Colombia, Cuba, Peru, Guatemala, Venezuela, and Ecuador had entered the WMA

International Code of Medical Ethics

Up to this point the proceedings of the assembly had presented no points of controversy, but the President said that now they came to a series of important reports which invited a lively exchange of views. The first of these was a proposed International Code of Medical Ethics, which incorporated the Declaration of Geneva, adopted by the general assembly in September, 1948, and a code setting out the duties of doctors in general and to the sick. Dr. Paul Cibrie, chairman of the committee which had elaborated the code, said that this was discussed a year ago. The code contained no more than general rules for the good practice of medicine. It was for each country to modify the wording for use within its borders, provided the principles of the code were respected. He moved that the code be approved.

Dr. P. Moran (Eire) took exception to a reference in the code to therapeutic abortion. The paragraph read:

"A doctor must always bear in mind the importance of preserving human life from the time of conception. Therapeutic abortion may only be performed if the conscience of the doctor and the national laws permit."

No one should have any right, except by judicial process, to pronounce sentence of death. The Association should not do anything which would make easier the path of the abortionist. Otherwise, where were they going as a profession? He moved that the reference to therapeutic abortion be omitted.

Dr. Paul Cibrie (France) reminded the last speaker that only a very severe condition would permit in certain countries the operation of therapeutic abortion. The abortionists were condemned implicitly in the declaration of Geneva.

Dr. W. Magner (Canada) supported Eire, although, he said, the question of therapeutic abortion had never been discussed by the Canadian Medical Association; and the Irish point of view was also supported by Dr. F. Sondervorst (Belgium), Dr. L. G. Tornel (Spain), and the Austrian and Portuguese delegates. Dr. J. A. Pridham said that Dr. Moran had stated that in no circumstances must a doctor commit murder. But murder could be committed either by deed or refraining from deed. If a doctor, after consultation with his colleagues, was certain that a woman would die unless therapeutic abortion was performed, and yet allowed the pregnancy to continue, might he not morally be guilty of murder? Dr. S. C. Sen (India) said that the question might arise whether to preserve the mother's life or the life of the foetus, and therefore it might be wiser to delete this sentence and leave it to the conscience of the professional man and the laws of his country. Dr. L. L. Davey (Australia) suggested that the governing consideration should be the welfare of the mother.

On a division the amendment to delete the sentence was lost by 19 to 22. Later, however, in view of this narrow vote, it was agreed to appoint a small committee to consider this whole paragraph, and on the following day the committee reported its view that the paragraph should simply read:

"A doctor must always bear in mind the importance of preserving human life from conception until death"—

leaving out any specific reference to therapeutic abortion, and in this form it was adopted by the assembly.

Duties of Doctors to the Sick

Dr. O. Rasmussen (Denmark) took up a statement in the report that it was unethical to participate in any plan of medical care "in which the doctor does not have complete professional independence." He objected to the word "complete," which in his view represented something unattainable. The assembly agreed to delete the word.

Dr. Sen found fault with the expression used in another paragraph, where it was stated that if a doctor found examination or treatment beyond his capacity he should "summon" another doctor. In his view the word "summon" had a legal connotation, but here the assembly adhered to the original text.

Various other emendations of the document were proposed, but the only one that found favour was a rewording of a paragraph as follows (on the proposition of the Luxembourg delegate):

"Under no circumstances is a doctor permitted to do anything that would weaken the physical or mental resistance of a human being, except for strictly therapeutic or prophylactic indications imposed in the interest of the patient."

The document was then approved, and it was agreed that it be left to national medical associations to modify the wording of the code, provided that any altered wording conformed to the principles which the code set out.

The WMA Bulletin

Before the assembly adjourned Dr. Morris Fishbein, editor of the WMA *Bulletin*, gave a brief report. Three numbers of the *Bulletin* had now been issued, and a proposal was being considered that six numbers be issued each year instead of four. He hoped that ultimately the *Bulletin* might prove to be the main financial support of the Association. It was the first medical publication to be published simultaneously in three languages. Incidentally, one of the editing difficulties was that the Spanish translations required 10% more words than the English or French. Dr. Fishbein gave some amusing instances of translators' difficulties. In another year

he thought the *Bulletin* would be on a firm foundation. Dr. Sondervorst (Belgium) said that in his own country they were very touchy about translations, which he hoped would continue to improve.

Postgraduate Education and Specialist Training

On the second day of its meeting the assembly, again under the presidency of Dr. Charles Hill, addressed itself to a report on postgraduate medical education and specialist training. The report—a long and exhaustively tabulated document—set out the results of a questionary to which the national medical associations in 32 countries had returned answers concerning the existence and establishment of standards for specialists, the period and type of training, details of examinations, certificates, schools, faculties, recognized specialties, and the opportunities for advanced education for doctors not interested in becoming specialists.

Dr. J. A. Pridham, in submitting this report, said that it embodied the results of work which only the WMA could have undertaken. The study had shown that the level of postgraduate education differed widely in different parts of the world, and so did the facilities for such education. He suggested to the assembly that here they had the possibility of doing something really valuable. It did not suffice for one country to go ahead in this field and leave other countries in a backward state. In view of the universal ethical standard which they had proclaimed, doctors in the more advanced countries should surely assist other countries to raise their own standards of education and practice. In that way they would be doing something to fulfil one of the main objects of the WMA—which was the maintenance of world peace.

He added that the report drew attention to the need for the continued education of the general practitioner, an important condition in any national scheme of medical care. It was obvious that there was a fear in many countries that the family doctor might be squeezed out, and that too large a proportion of men, on qualification, might seek to become specialists.

Dr. A. P. Cawadias (Greece) spoke on the education of the specialist. With the development of medical science the general consultant was disappearing. In future they would speak of specialists only. He emphasized the need for a generous pre-professional education. In the Greek universities there were severe examinations before professional education was embarked upon. He believed that this background of general culture was even more necessary for the specialist than for the general practitioner. Something should be done to ensure that examinations for specialists exacted a certain standard of general culture.

Dr. Paul Cibrie (France) declared himself not in entire agreement with this Athenian point of view. The general culture of the general practitioner should be on the same level as that of the specialist. He was not in favour of cultural hierarchies in the medical profession. General practitioners must not be regarded as at the bottom of the ladder and specialists as at the top.

Dr. F. Sondervorst (Belgium) objected to a proposal in the report that where a doctor's remuneration came mainly from a State social insurance scheme that scheme should finance his refresher course. In his view the course fees and expenses should be paid by the doctor himself or provided by scholarships or fellowships.

"Looking Down" on the General Practitioner

Dr. S. C. Sen (India) said that there seemed to be a tendency for specialists to regard themselves as belonging to the higher strata of the profession, and a tendency also to extend the period of specialist training. He believed that in Austria they insisted upon six years' additional education if a man was to become a specialist. Medical education was already sufficiently expensive and time-consuming. He thought they should emphasize the minimum standard and not expect to decide on the maximum. He deplored a tendency to "look down" on general practitioners. In the United States they were now setting up specialists in general practice, and an academy of general practice had been established, recognized by the American Medical Association, and requiring its members to undertake 150 hours' training every three years. The background of general culture had been mentioned, but culture should not be narrowly interpreted as a matter of leisure and books, but rather of tolerance and a wide outlook upon life. He suggested also that a knowledge of ancient Eastern philosophies should be regarded as a cultural equipment equal to Latin or Greek.

Dr. Morris Fishbein (United States) objected to a suggestion in the report that "wherever possible there should be general practitioner hospitals, or general practitioner beds in ordinary hospitals where he [the general practitioner] may attend his own cases and call in the help of his specialist colleagues." It was an error to propose hospitals for general practitioners as distinct from hospitals in which both general practitioners and specialists carried on their work. This proposal would promote disruption in the profession. The tendency in countries where there was a State medical service had been to make the general practitioner "second class." He was considered to be one who merely directed cases to a specialist. Yet if the progress of medicine were studied in recent years the tendency seemed to be to give the general practitioner increasingly the care of cases which formerly went to the specialist. This had come about because of the advent of antibiotics, also blood transfusion and the use of blood products, as well as other advances. In the field of otolaryngology, for instance, little remained for the specialist except such things as the fenestration operation, and in the field of dermatology the specialist was left with only a few conditions to which he could give a name but for which he had no treatment! There should be complete integration of the general practitioner in the hospital services, with adequate representation on the staff of the hospital and on the executive medical committee.

Dr. L. G. Tornel (Spain) also was of the opinion that the general practitioner should be ranked as highly as any specialist. Dr. K. E. U. Jäämeri (Finland) held the same view. In his country too much importance had been attached to the scientific status of those who held posts in institutions. Dr. Dag Knutson (Sweden) said that it was not so much that others looked down upon the general practitioner as that the general practitioner seemed inclined to look down upon himself by referring patients to specialists more and more quickly, as though afraid to handle them himself. The general practitioner was the backbone of medicine, but if he was content to accept an economically lower status than the specialist he would continue to be looked down upon.

Dr. W. Cline (United States) proposed the following words as an improved version of what was stated in the report.

"In addition hospitals should welcome visits from general practitioners. Posts should be made available to them. Such posts are of benefit both to the specialist and the general practitioner. There should be general practitioner beds in ordinary hospitals, and general practitioners should be integrated into the hospital service. In this manner a general practitioner will become a better doctor and have more interest in his work."

Asked what he meant by an "ordinary hospital," he said that he meant one from which cases requiring certain special care, such as cases of mental disease and perhaps tuberculosis, were excluded. Asked if he would include teaching hospitals, he said that this would depend upon local circumstances. Some hospitals found it advisable for the training of medical students to utilize the services of general practitioners, although the bulk of the teaching was done by specialists.

Professor K. Fellinger (Austria), Dr. O. Rasmussen (Denmark), and Dr. F. Wibaut (Netherlands) said that in their countries owing to the system of hospital administration it would be impossible to put this proposal into effect.

Dr. Routley (Chairman of Council) said that they were losing sight of the fundamental principles of the WMA. The Association did not dictate to any member-association. It was for each association to apply the spirit of the resolution in the way it found best.

The version suggested by Dr. Cline was adopted, with the deletion of the word "ordinary," and with the insertion of the words "where possible" before "posts should be made available to them."

Period of Practice under Supervision

Certain recommendations of the committee were adopted. The first was that every doctor, after obtaining his licence to practise, should spend a period during which he practised under supervision, usually in hospital, but possibly as assistant to a general practitioner. Dr. Harvey Pirie (South Africa) said that in his country the importance of this had recently been recognized, and it was now legally compulsory for medical graduates to do a year's internship or occupy some approved post before they could be admitted to the *Register* and take up independent practice.

It was also agreed that to become a specialist it was necessary to obtain an adequate postgraduate training, particularly in the field of the specialty. National medical associations were requested to endeavour to secure by mutual arrangements that opportunities for postgraduate studies and practical experience should be made available to members of the profession from other countries. It was realized that to accomplish this it might be necessary in the respective countries to overcome legal and other difficulties.

Dr. H. Guy Dain said that one of the provisions of the new Medical Act in Great Britain would be to provide that a graduate of another country coming here for further study might be placed on the British *Register* temporarily whilst he was engaged in his studies here in order to give him the opportunity for taking responsibility for cases without offending the principal Medical Act. He would be allowed to practise in this country for a limited period and be able to take charge of cases because he would be officially on the *Register*.

The final recommendation on this subject, which was agreed to, was that the national medical associations and the various international organizations should arrange an exchange of information regarding vacancies and opportunities for graduate and postgraduate study in foreign countries.

Progress reports were submitted by the Committee on Medical Care and Allied Subjects (dealing especially with efforts to improve the medical libraries of the world), and the Committee on Ways and Means of Securing Publicity. It was reported that a Committee on Standard Nomenclature had been appointed.

Reports of Observers on Intergovernmental Bodies

Dr. J. Maystre, the Association's observer on WHO, gave a brief account of the WHO assembly in Rome, and said that the relations between the two bodies were permanent and official. An inquiry of WHO on the use of habit-forming drugs had been entrusted to WMA.

Dr. M. H. Hafezi, of WHO, brought the best wishes of its Director-General, and spoke of collaboration in many subjects. The WMA was WHO's main link with the medical profession.

Dr. H. Guy Dain asked whether WHO was proposing to deal with questions of medical ethics in any sense through a committee. In Great Britain they would resent having any code of medical ethics imposed upon them by a partly lay body.

Dr. Maystre said that when this matter came before the Executive Council of WHO he drew attention to the work of WMA, and the Director-General was instructed to hold it in abeyance until WMA had taken some action. He was also asked about the action of WHO in respect of an international pharmacopoeia, and said that WHO was attempting only to formulate nomenclature that could apply to all countries, but the list of remedies was not limited.

Dr. Fishbein said that he was a member of the board of directors of the *U.S. Pharmacopoeia*. The Commission of WHO which was concerning itself with an international pharmacopoeia was composed of representatives in the field of pharmacy and pharmacology and had no representative of medicine. The proposal to have a selected list of remedies—a list of 141 drugs for which common names might be chosen throughout the world—had various implications. In some countries endeavours were being made to restrict the right of the physician to prescribe what he thought best for the patient. This must limit choice in prescribing and contribute to the lowering of the status of the general practitioner, and would tend also to inhibit progress in the field of research.

Dr. Hafezi mentioned the care with which experts were selected for the committees of WHO. With regard to drugs, it was not proposed in any sense to replace national pharmacopoeias, but only to endeavour to arrive at common standards.

The President said that they were grateful to Dr. Hafezi. He would understand that national medical associations by tradition were vigilant in observing what their respective governments did, and that assembly as representing the medical associations of the world would be equally vigilant in watching the work of WHO. But they looked forward to the closer collaboration which had been promised.

Dr. Maystre also gave a report as observer on ILO and its activities in social security. Dr. Manuel de Viado, who attended as an observer from ILO, also brought greetings from the Director-General, and said that ILO had fully documented information about the medical services of 62 countries. It was anxious to collaborate and exchange information.

Dr. Maystre gave one further report, as liaison officer at the recent Diplomatic Conference for the Establishment of International Conventions for the Protection of War Victims, held at Geneva. He was asked about the position of doctors who were prisoners of war, and said that a number of medical prisoners would be exchanged for similar personnel from the enemy country, but some prisoner-of-war doctors would be retained to look after their compatriots in prison camps. He believed the conditions as established by the new conventions were better than those prevailing during the recent war.

The final observer report was from Unesco, on which Dr. Cibrie made a brief statement. He said that collaboration with Unesco was likely to be very useful both for that organization and for their own, and it was important that the contacts should not be reduced.

Mme. I. M. Zhukova, who represented Unesco as an observer at the assembly, brought the greetings of the Director-General, and gave an account of the work of Unesco, particularly in initiating—at a time when there was no other body to undertake the task—the co-ordination of international medical congresses. She said that Unesco had set up an independent non-governmental liaison committee between itself and WHO, with its headquarters in Brussels. There was no intention to interfere with the agenda of international medical meetings, but only as far as possible to arrange time and place in such a way as to afford the maximum convenience to those attending. A calendar of international congresses would be published.

Dr. Sen asked how many members of the medical profession were on Unesco committees. On the national commission in the United States he understood that there was no representative of the American Medical Association. What was the composition of this independent body established by Unesco and WHO?

Mme. Zhukova said that it was for the national medical associations to ask for representation on commissions of Unesco.

Dr. Sondervorst (Belgium) testified that the new committee set up in Brussels was non-governmental. He hoped that the Secretary-General of WMA would be instructed to get in contact with this new organization with a view to participation.

Dr. Routley (Chairman of Council) said that the Council was not fully informed when it passed a resolution on the subject of the permanent committee for the co-ordination of international congresses of medical science. Therefore he suggested that the debate be adjourned, and that the whole matter be referred back to the incoming Council for reconsideration. The WMA were concerned to secure the closest co-operation with all other world bodies which had a place in the field of health.

It was agreed to remit the matter for the consideration of the incoming Council.

Next Meeting of the Assembly

The President said that it had already been agreed that the United States should be selected as the country for the 1950 session of the assembly, but this required confirmation by the present meeting.

Dr. Routley formally moved and Dr. R. L. Sensenich (United States) seconded that the meeting in 1950 be held in the United States, and this was agreed to.

Dr. Taalman Kip (Netherlands) said that he did not oppose the motion, but at the same time he pointed out the time and expense involved for European and other delegates attending a meeting in the United States. The Secretary-General said that the meeting would be held in October, at a period of the year when reduced passenger fares came into operation, and this reduction might compensate for the disadvantage arising out of devaluation. Moreover, in America they were anxious to help delegates from the sterling area, and a certain amount of hospitality would be forthcoming.

The second day of the assembly then concluded. On the following day there were no meetings, and an excursion to Windsor, Eton, and Hampton Court was arranged.

Social Security and the Medical Profession

The last day of the assembly, October 14, was devoted to the discussion of a report on social security, the work of a committee of which Dr. Charles Hill was chairman and Dr. Paul Cibrie, Dr. P. Glorieux, Dr. E. L. Henderson, and Dr. Dag Knutson were the other members. The report was presented by Dr. Hill, Dr. T. C. Routley temporarily presiding.

Dr. Hill said that wherever schemes of social security, embodying medical services, were being evolved, the medical profession was presented with the problem of preserving—in the interests not of the medical profession but of the public—the essential freedoms of the profession in the conduct of its work. Bearing in mind that it was not the role of the World Medical Association to dictate to its member-associations the line they should take in dealing with schemes in their respective countries, his committee had begun the preliminary work of survey, and the report now presented was a factual summary of the conditions in 24 countries. Governments were closely associated together in these matters, each government making a careful study of what was going on elsewhere. Information was passed from government to government, and because of this intergovernmental activity it was only right that the medical profession in each country should be informed of what was going on elsewhere. The function of the World Medical Association was to provide an international forum for the expression of the views of the profession on relations with governments. It was important that the profession should be informed of the trend of governmental activities, should maintain a wise vigilance, and should be prepared to resist tendencies which threatened the freedom of the profession.

National Health Service in Great Britain

Dr. H. Guy Dain made a short statement on the early experience of the new National Health Service. The British Government had been warned beforehand that there was not sufficient provision to establish a free service of all medical requirements for the entire population in one jump, but the Minister believed in "the method of teaching you to swim by throwing you in and seeing what happens." The profession in Great Britain had urged a general medical service for the nation for many years, but it had not expected that a free service for the entire population would be brought in other than gradually. The inevitable had happened, that where a community found itself entitled to a free service it made immediately the maximum demand. The Service had been inaugurated without a sufficient provision of doctors, nurses, hospital beds, and material equipment. The consequence was that doctors had been overworked, there were long waiting-lists at hospitals, and with regard to material provision, such as spectacles, the demand had far outstripped the supply. Some means must be found of bringing the demands within reasonable control. It had been suggested that a small, but not prohibitive, charge should be made for various articles supplied.

The position of the medical profession had been made very difficult. The remuneration of the general practitioner had not been finally settled, and consultants and specialists had only recently been acquainted with their terms and conditions. The profession held that the freedom of the patient to choose his doctor was essential to the progress of medicine and to the proper relationship of doctor and patient. They had opposed from the beginning any idea of a salaried service, because that inevitably limited the right of choice. The doctor should also be free to act within his discretion as to the kind of practice he undertook and the place in which he practised. This had been attained in the British system. The profession also considered it essential that private practice should be continued side by side with any State service. In this respect they had only partially succeeded, and the opportunities for private practice in the field of general practice were limited, partly because the Government would not allow the private patient to obtain his drugs and dressings within the Service. He was convinced that private work outside the State Service should be maintained. A few hospitals privately owned and supported were independent of State control and possibly represented the beginning of a free service outside the State Service.

Great Britain, with a long history of contract practice, had approved a system of capitation payment for general practitioners; he knew that this method was not favoured in some other countries, but it did save the doctor from being dependent on the State or on a superior officer in the State Service. In a Service which embraced 95% of the population, and upon which so large a proportion of the doctor's income depended, it was important that doctors should be free to express themselves in any way they liked, not only about medicine in general but about the Service itself.

What had been the effect of the Service on medicine and on doctors generally? At the moment there was disorganization. The rush of work was such that many doctors complained that they could not give their patients as much time and attention as they desired. That was a temporary phase which would be corrected as doctors became better distributed. On the subject of remuneration, the size of the general practitioners' pool had not yet been agreed; the total amount was still the subject of negotiation. The difficulties of the rural practitioner had been largely overcome by an addition to what was called the mileage fund, but which in fact included the time as well as the mileage factor. The doctors who had suffered most were those in practice in the higher-class residential areas. The private patients from whom they had formerly drawn their income were now National Health Service patients. Until some readjustment had taken place in the number of doctors practising in such areas, and some weighting of the capitation fee was made for the first thousand patients on a doctor's list, so that a doctor who had necessarily a small list owing to the circumstances of his area would not be so gravely disadvantaged, this difficulty would continue.

This was only a brief outline of the "teething troubles" from which they had suffered in Great Britain during the first year; it might have some interest for those in other countries who might have to face similar developments.

Continental Opinion

Dr. Paul Cibrie (France) objected to the capitation fee method of payment, which he thought put the doctor at the mercy of the patient. In France and Belgium payment was made on an item-of-service basis according to a fixed tariff. Dr. P. Glorieux (Belgium) said that in his country a scheme of health insurance was started without any consultation with the medical profession, but the cost was considered to be too high, and now a commission was sitting to consider the question anew. Dr. O. Leuch (Switzerland) considered that social insurance was needed only for people below a certain economic level; other persons should be treated on a voluntary or private basis. In Switzerland social sickness insurance embraced the whole family, and specialist and hospital services were included.

Dr. Dag Knutson (Sweden) described the projected Swedish programme of comprehensive and compulsory social insurance, with the transformation of all doctors into Civil Servants controlled by the State. The Swedish Medical Association had set up a committee of doctors with experts in economic questions to work out the cost of the proposed service. This was difficult because of the vagueness of some parts of the Government's proposal. But it was believed that the inauguration of the

programme would cost £70 million, and the annual cost would be over £50 million. At present taxation in Sweden was at a forbidding level, a number of people paying from 40 to 60% of their total income in taxation. In the view of the Swedish Medical Association, which favoured an extension of the insurance scheme which already covered 60 to 65% of the population, the proposed system was incompatible with free choice of doctor.

Dominion Experience

Dr. W. Magner (Canada) said that in May, 1948, the Prime Minister of Canada announced a national health programme in which some 30 million dollars a year was to be made available to the Provinces for the improvement of health services. The Canadian Medical Association, which had for long been on record as approving the principle of contributory health insurance, met in June of this year and formulated its policy, which he read to the assembly. This favoured a system of health insurance, and declared that the Canadian Medical Association would oppose any Act modelled on the British Act and any conditions of general practice such as were imposed on British general practitioners. Government subsidies for the medical care of the lower income groups were welcomed.

Dr. L. L. Davey (Australia) said that the Pharmaceutical Benefits Act, which provided free pharmaceutical benefits according to a formulary and on the prescription of a doctor, was apparently a dead letter, following a recent decision of the courts. The National Health Services Act had not yet been proclaimed; it was only an enabling measure, and the details of the Service would be determined by regulations, which had not yet been promulgated. The medical profession had laid down certain conditions, which were unacceptable to the Government. In Australia the poorer no less than the middle and upper classes had always been assured of service.

Dr. J. H. Harvey Pirie (South Africa) said that ten years ago the Medical Association of South Africa put forward a scheme for a National Health Service; he doubted whether they would put forward a scheme of the same kind to-day. They were more likely to call for a system of national insurance so far as the white population was concerned. The medical profession in South Africa had won the first round of its fight against an Act whereby all persons would have had a complete free hospital and medical care service, and had now a breathing space in which to organize themselves further.

The Issue in the United States

Dr. W. Cline (United States) said that any scheme on a comprehensive federal basis in the United States would be beset with difficulties on account of the great disparity as regards population density in the different regions. The complications were greater than in a smaller and more homogeneous country. The American Medical Association believed that progress in medicine could be best promoted by preserving the freedom of the profession. It had not accepted any participation with the Federal Government in supplying coverage for groups that could not easily afford medical attendance. Rather it looked upon the indigent as the responsibility of the local community, their medical care to be provided by doctors at no charge or such charge as could reasonably be made, and their care in hospital to be provided by public or charity institutions. With this end in view the profession had endeavoured to develop and enlarge the voluntary insurance system. There were a number of voluntary plans in the States adapted to the economic circumstances of different communities. Various proposals had been laid before them during the last ten years for systems of compulsory health insurance, somewhat similar to the Health Service Act in Great Britain, and likely to confer upon one individual or department powers similar to those of the Minister of Health in this country. It had been stated that large sections of the current proposals before Congress had been taken bodily from the British Act. This was regarded as a purely political move on the part of people concerned to attract votes. Compulsory health insurance was "the foot in the door." The result would be Government dictation in medicine. The profession was determined to fight the domination of medicine by the Government, and already the efforts it had made had brought about a material change in public opinion. Apart from this, the other issues involved in social security were not the direct concern of the medical profession.

Dr. S. C. Sen gave a brief account of the situation in India. There were at present about 50,000 qualified doctors for a population of 350 million, but in addition there were five times that number of practitioners practising the ancient systems of medicine. The Government of India had in preparation a scheme to provide a medical service with cash benefits for sickness, maternity, and occupational injury for about five million industrial workers. It was expected that funds would be derived from compulsory insurance contributions. It was not yet known whether medical treatment would be provided through a panel system or by full-time medical officers.

A Continuing Study

In closing the discussion Dr. Hill said that the discussion had shown that at future assemblies a prominent subject on the agenda on each occasion must be social security. The exchange of information was not only of value in keeping the record straight and in stimulating national medical associations to interest themselves in this problem, but it would have the effect of sparing the necessity for criticisms based on lack of information or on inaccurate information. In this report a beginning had been made in the collection of facts. It would be necessary to compare the facts so collected with those obtained by governmental and intergovernmental organizations. This work was the most important to which the Association had set its hand.

The various factual reports were adopted, and the assembly agreed on the recommendations of Council to invite each national member-association to furnish details of the total annual cost of the social security scheme in operation in its country or of the estimated total cost of any proposed scheme, and of the proportion of the national budget which the cost of any such scheme involved. The national associations are also to be asked to give their considered opinion on the results of social security based on the experience gained in their own countries, and to furnish various other information. The information thus forthcoming is to be circulated in a quarterly bulletin for the information of national member-associations.

The Chairman of Council (Dr. Routley) expressed to Dr. Hill and his committee the thanks of the assembly for their labours.

Closing Proceedings

The assembly, which meets in the United States in 1950 and in Sweden in 1951, had three invitations for 1952—from Canada, Cuba, and Greece. The choice of venue was left to the Council.

Dr. R. L. Sensenich (United States) moved, and Dr. L. G. Tornel (Spain) seconded, that Dr. Elmer Lee Henderson, of Kentucky, U.S.A., Fellow of the American College of Surgeons and President-elect of the American Medical Association, be President-elect of the World Medical Association, and this was agreed to unanimously.

Dr. Henderson, in accepting the nomination, said that in the United States they had great hope for the future of the WMA, not only from the standpoint of promoting medical care in all countries of the world, but from that of establishing world peace.

The three retiring members of Council—Dr. P. Cibrie, Dr. Dag Knutson, and Dr. J. A. Pridham—were re-elected.

Dr. Henderson then proposed a vote of thanks to the British Medical Association for the arrangements it had made for the assembly, to Dr. Charles Hill for the excellent way in which he had presided over the assembly, to the interpreters for their able assistance, and to the Ladies Committee for providing entertainment for ladies accompanying the delegates.

The vote of thanks was carried with enthusiasm, and Dr. Hill, after acknowledging the compliment on behalf of the British Medical Association, expressed his own thanks to the Secretary-General (Dr. Louis Bauer) and his staff for all that they had done to ensure the outstanding success of the third assembly.

COUNCIL DINNER

At the conclusion of the assembly of the World Medical Association on October 14 the Council of the British Medical Association gave a dinner in the Great Hall in Tavistock Square. It was the first occasion since before the war that a Council dinner has been held in the building, and the presence of so many delegates from foreign countries, with their ladies, gave special significance and colour to the gathering. The guests, to the number of 211, were received by Dr. E. A. Gregg, Chairman of Council, and Miss M. Gregg. In proposing the toast of the World Medical Association Dr. Gregg said what a pleasure it had been to the Association in London to act as hosts and to have an opportunity of returning the welcome which was given to the British guests at the two earlier assemblies in Geneva and in Paris. Another reason why the B.M.A. was glad that the international body had come to London was because it had seen fit to honour Dr. Charles Hill by making him its President. In the British Medical Association they held Dr. Hill in very high affection. He was a wonderful man and he was going far before he had finished his course. They were proud and honoured that it was in the British Medical Association he proved his abilities and found his voice.

Dr. Charles Hill remarked that it would be an under-statement for him to say that he was proud to be in a position to respond for the WMA, particularly when its meeting was held in that building. It was perhaps inevitable that while enjoying the temporary glory of the chair during the past week he should have made comparisons between the assembly of the WMA and the Representative Body. The former, though embracing many nationalities and races, from Iceland to Australia and Cuba to Pakistan, was relatively placid. It lacked the tempestuous tone which had characterized recent Representative Meetings. This was partly due, no doubt, to the fact that it had been necessary to interpret all the speeches in another language, and during the interpretation any feelings which might have been aroused had a chance to simmer down. One thing which his temporary occupancy of the chair had shown him was that the wisdom and efficiency of a Chairman or President were largely due to the promptings of an efficient Secretary. He had noticed a certain succinctness about Dr. Louis Bauer's adjurations to the occupant of the chair which he himself would endeavour to imitate when he resumed his secretarial seat. During the week the assembly had discussed an international code of ethics, postgraduate medical education, and social security, but the one thing that mattered most of all was the contribution which such meetings made to international relations and world fellowship.

Dr. T. C. Routley recalled the inaugural meeting held at B.M.A. House in 1946, when Sir Hugh Lett (whom they were glad to see present that evening), with great patience and tolerance, assisted at the birth of this lusty infant. Dr. Elmer Henderson, President-elect, made a further response, and said with what pleasure they would welcome the next assembly in the United States.

Dr. L. G. Tornel then in a tornado of Spanish eloquence proposed the health of the British Medical Association, speaking of England as a country of noble traditions and love of freedom. Dr. Paul Cibrie added a few words in praise of the generous hospitality and what he called the graciousness of the British hosts. A response was made by the President of the British Medical Association, Dr. C. W. Curtis Bain, who spoke of the broadmindedness of the WMA, as exemplified in the fact that, although the subject of therapeutic abortion had come forward and had elicited sharply contrasting views, it had been quickly settled in what they used to think was a peculiarly British way, but which was evidently a world medical way, of compromise without forfeiture of principle.

To the great pleasure of the company Sir Lionel and Lady Whitby arrived before the proceedings closed, having come direct from the boat which brought them back from their American and Canadian tour. Sir Lionel Whitby in a few graceful words proposed the health of the ladies, remarking on the contribution they could make to international peace and fraternity, and a response was given by Mme. O. Leuch, of Switzerland.

HEALTH CENTRES

PRIVATE PRACTICE AMENDMENT

The Minister of Health tabled an amendment for the Report Stage of the National Health Service (Amendment) Bill the effect of which is to enable a general practitioner practising from a health centre to see and treat private patients there. The amendment reads:

Page 22, line 9 (Schedule), at end, insert—

At the end of paragraph (*a*) of subsection (1) of section twenty-one (which requires facilities at health centres to be available for the provision of general medical services), there shall be inserted the words "and, on such terms and conditions as may be determined by the Minister, for the provision by medical practitioners of such other personal medical services (if any) as may be so determined in the case of a particular health centre."

Opinions differ on whether private practice from a health centre is desirable or not. Advocates of the scheme point out that practice expenses may be reduced, since the doctor would not need to have a surgery and other facilities at his home. On the other hand some fear that if private patients are treated at health centres they may cease to enjoy those few advantages that induce them to remain as private patients, and that therefore private practice would disappear.

HOSPITAL DENTAL STAFF

The Ministry of Health has informed hospital boards that they should now offer permanent contracts to all grades of dental officer on their staffs in accordance with the published Terms and Conditions of Service.

DISCIPLINE AND PUBLICITY

Proceedings before medical service committees are private, and reports of these committees go to executive councils for consideration. A circular from the Ministry of Health states that the Press should not be admitted while an executive council is discussing a medical service committee's report, but they should normally be admitted when a decision has been reached, and told the decision. The Minister suggests that it might be convenient if the council were to publish a summary of the case and of the findings.

Further Publicity

In due course the council is notified of the Minister's decision. The council may then give further publicity, and the Minister considers that that would be desirable in serious cases. A summary of the case could be published, together with a report of the Minister's decision.

No Names

The circular states that at no stage should the names of the parties to the proceedings be mentioned, or particulars which might lead to their identification.

OCCASIONAL ATTENDANCE ON ARMY PERSONNEL

The Association has received several complaints in recent months in cases where doctors have experienced considerable delay in obtaining payment from Army funds of fees due in connexion with the treatment of soldiers "sick on leave" or on the lodging list. The War Office has pointed out that no undue delay should occur if the completed Army Forms O.1667 are sent to the Assistant Director of Medical Services of the local district, or to the Deputy Director of Medical Services of the Command in which the doctor is practising. Members are advised, therefore, to follow the procedure outlined above and not to send accounts to the officer commanding

the unit concerned (which, however, is still the procedure for R.A.F. personnel). Addresses of D.Ds.M.S. are as follows :

Headquarters, Eastern Command, Hounslow, Middlesex. Headquarters, Northern Command, York. Headquarters, Western Command, Chester. Headquarters, Southern Command, Salisbury, Wilts. Headquarters, Scottish Command, Edinburgh.

Addresses of A.Ds.M.S. of local districts can be obtained from the D.D.M.S. of the Command concerned. Initial requests for copies of A.F.O.1667 should be made to these officers and not to the officer commanding the soldier's unit. The forms are also obtainable from the local executive council.

Questions Answered

Circular to General Practitioners

Q.—*I am in full-time employment as a surgeon, and shortly changing over to part-time hospital work and entering private consultant practice. What form of circular may I send out to the general practitioners of the district acquainting them of this fact?*

A.—There is no ethical objection to a circular letter being addressed to any practitioners in the area who may reasonably be expected to be interested. The circular should be brief and should confine itself to a statement (for example) that "Mr. X is now available to see private surgical patients by appointment at (address). Telephone No.: 1234." The letter should be enclosed in an envelope, which need not be sealed.

The ethical considerations to be borne in mind are such brevity and simplicity of announcement as are consistent with clarity, and a reasonable restriction of the field of circularization.

Examining Hospital Employees

Q.—*I am a whole-time medical registrar at a teaching hospital and examine weekly, prior to their engagement on the hospital staff, domestics, porters, cooks, stenographers, etc. Am I entitled to any fee for performing these examinations, and, if so, what is the fee?*

A.—A whole- or part-time medical officer in contract with a board of governors is not entitled to claim a fee for the examination of employees or prospective employees of the hospital where he is engaged.

No Fee Allowed

Q.—*Is a whole-time officer forbidden from charging a fee for a private consultation carried out in his own home outside the usual hospital working hours or at the week-end?*

A.—A whole-time officer is not entitled to undertake private practice. This is laid down in the Terms and Conditions of Service of Hospital Medical and Dental Staff, paragraph 14.

Practising Elsewhere

Q.—(*a*) *I am in general practice under the National Health Service Act and I wish to change from one area to another. How do I go about it?* (*b*) *Will my compensation be based on my new practice or my old one?*

A.—(*a*) If a general practitioner giving general medical services under the National Health Service wishes to leave his present practice he may do so by giving three months' notice to the clerk of the local executive council or such less period as may be permitted in a particular instance.

The practitioner may either study the advertisements of vacancies and make application for those that interest him, or he may apply through the local executive council to the Medical Practices Committee for permission to practise in the area of his choice. If this is not a closed area, the consent of the Medical Practices Committee is automatic unless the number of applicants exceeds the number required for the area to be adequately doctored. Application may also be made to the Director of the Medical Practices Advisory Bureau at B.M.A. House, who may be able to put him in touch with a practitioner who wishes to obtain a successor.

(*b*) The amount of compensation to which the doctor is entitled (and on which he receives payment of interest) is assessed in regard to the practice in which he was engaged on July 5, 1948, and does not alter. Under the Act it is payable on retirement from practice as a medical practitioner providing general medical services under Part IV of the Act, but payment cannot be made at the present time, as the total amount of all claims for compensation is not yet known. A change from one practice to another does not constitute retirement for this purpose.

Certificates for Corsets

Q.—*In reference to the Questions Answered paragraph "Certificates for Corsets" in the Supplement of August 27 (p. 115), I should be grateful if the position be still further clarified. Does a prescription for a corset for any disability exempt the garment from purchase tax, or has the disability to be one of a number of named disabilities laid down by the Government department concerned?*

A.—Customs and Excise Purchase Tax Exemption Schedule 78 sets out those disabilities which on production of the necessary medical certificate exempt the purchaser from purchase tax on a corset.

Retrospective Pay

Q.—*With reference to retrospective pay, am I entitled to this as regards a post to which I had been appointed before July 5, 1948, but which did not become vacant till a little after this date, and where the salary was raised after the completion of my appointment? If I am entitled to such pay, where and when am I to apply?*

A.—In general the salary of hospital medical staff will be adjusted in accordance with the practitioner's recent grading on the basis of the terms and conditions of service retrospectively to July 5, 1948, or to the date of appointment, whichever is the later. Where different posts have been held, the adjustment will take into account the grading of each appointment. Thus in the case of registrars the posts held from time to time since the appointed day will be reviewed and classified in accordance with the new grading and remuneration then adjusted retrospectively. In the case of house officers, the period since registration will be divided into six-monthly periods, the salary for the first six months being calculated at £350, for the second at £400, and thereafter at £450 per annum.

The practitioner should apply to the employing authority for payment of any sum to which he is entitled in respect of the expired appointment.

National Insurance Contributions

Q.—*At present I am doing a locum for a doctor who had a car accident. Prior to this I had done a hospital job, and between ending it and obtaining the locum I was unemployed for a week. This locum finishes this week, and when it ends I intend to take driving lessons, during which time I do not wish for another position. I intend, therefore, to be unemployed for about a month. I would be much obliged if you would let me know what contributions I have to make under the National Insurance Acts for the period I was unemployed before the locum, and for the period of my locum; and what the position is with regard to the National Insurance Acts for the subsequent period of virtual unemployment. I would also like to know the position with regard to superannuation for the period of my locum. If you could clear up these points I would be most grateful.*

A.—As an employed male person your employee's contribution is 4s. 11d. per week. When unemployed you pay 4s. 8d. as a non-employed person unless a "credit" is obtained by registering as unemployed at an employment exchange. The employment of a short-term locumtenent by a principal does not involve any superannuation scheme. This differs from the case of an assistantship. If you have previously been subject to a superannuation scheme you should ascertain from your previous employer the position regarding past payments.

Retrospective Pay for Housemen

Q.—*Is retrospective pay up to the present scale of remuneration payable from July, 1948, to persons employed as house-physicians at that time (and for the remainder of the year)?*

A.—The Ministry has laid down that, in applying the new rates for house officers retrospectively to the appointed day, the period since registration during which posts in this grade have been held should be divided into six-monthly periods (irrespective of the period of tenure which in practice attached to the posts). The remuneration for the first six months after registration is calculated at the rate of £350 per annum, for the second six months at the rate of £400 per annum, and thereafter at the rate of £450 per annum.

Therefore the questioner would appear to be entitled to retrospective adjustment of salary at the rate of £350 per annum in respect of the period July 5–August 31, 1948 (i.e., that part of his first six-monthly appointment which comes within the National Health Service), and at the rate of £400 in respect of the period September 1–December 31. The principle of retrospective application of the terms has been determined by the Ministry, and the practitioner should press his claim with the hospital.

HEARD AT HEADQUARTERS

A New Word

It came with dreadful suddenness upon our ear recently in listening to a public address by one of the principal medical officers of the Ministry of Health—the word "pathologize." He spoke of a patient being "*x*-rayed and pathologized," meaning, of course, submitted to various pathological examinations. This sort of thing comes trippingly to the tongue. It is not so long ago that the word "hospitalize" was minted. "Anatomized" is, of course, already in the *Oxford*. It will not be long before a patient is "clinicized" or a pregnant woman "obstetricized."

Sweden To-morrow

A few days spent in Stockholm recently were sufficient to reveal to one the outstanding excellence of the Swedish hospital system. In Sweden, we were told, only 3% of hospital beds are in private institutions. Sweden is looking forward next year, or in 1951, to the introduction of a comprehensive and compulsory health scheme. Every Swedish citizen will then be entitled to free treatment at the public hospitals. Certain basic medicines will be dispensed free; others at half price on presentation of a doctor's prescription. Three-fourths of the doctor's fee will be paid for under the scheme, as well as the travelling expenses of the patient, with compensation during the period of his illness, and the patient will be able freely to choose his doctor. Under the present health insurance scheme about 60% of the adult population participate, and the health insurance or sick benefit organizations, which are recognized by the Government, pay two-thirds of the doctor's bill. Sweden's great problem is the shortage of doctors—4,000 to serve a population of 7,000,000, a ratio of 1 to 1,750.

Insomnia

A patient seeking sleep that knits up the ravelled sleave of care hopes to get help from the Health Service in a novel way. A doctor tells us that he has received the following letter from her: "Dear Dr. X, I wonder if you could possibly let me have a certificate to get a small electric massage machine through the National Health Service. I have been suffering from insomnia during the last year or so, and do not want to take any tablets, etc., in order to cure this. I am in fact rather nervous of them. But I do think that about 10–15 minutes' massage every evening before going to bed would have a very soothing effect, and would do the trick. If you could possibly help me in this way I would be very grateful."

The Language Difficulty

The language difficulty was well surmounted at the WMA, although the delegates who came to London spoke, between them, at least sixteen languages in their own homes and practices. Here they spoke remarkably well in French or English, and some of them in both, interpreting their own speeches. Interpretation doubles the length of the proceedings, but, as Dr. Hill suggested, it may do something to becalm them. The WMA interpreter, Dr. Gérin-Lajoie, of Montreal, was a two-way man. Usually in international assemblies two interpreters are employed, one to turn French into English and the other to turn English into French, but Dr. Gérin-Lajoie did it both ways without turning a hair, and was as fresh as paint at the end of the day. Miss Roverano also gallantly assisted on the Spanish side, though her interpretations were mainly *sotto voce* for the benefit of the two or three delegates who needed the Spanish.

GENERAL MEDICAL COUNCIL

ELECTION OF DIRECT REPRESENTATIVE

Practitioners in England and Wales will receive within the next few days voting papers for the purpose of electing a Direct Representative of the profession to the General Medical Council to fill the vacancy occasioned by the death of Dr. J. W. Bone. Dr. O. C. Carter, of Bournemouth, has been chosen as the Association's candidate, and his Election Address is set out below. All members of the Association are asked to cast their votes for Dr. Carter.

Dear Sir or Madam,

I have the honour to offer myself for election as a Direct Representative of the profession on the General Medical Council. I believe the best qualifications a candidate for the office of Direct Representative can have are a long and wide experience in the practice of his profession and a sound knowledge of the many difficult and varied problems that confront the profession. I believe that reforms are needed in the constitution, functions, and procedure of the General Medical Council, and I support strongly the recommendations of the British Medical Association, among which appear the following:

Every complaint made to the Council should be supported by an affidavit.

The Council should be empowered and required to establish two distinct and separate committees to be known as (*a*) the Penal Cases Committee; (*b*) the Disciplinary Committee.

No member of the Penal Cases Committee should be permitted to sit as a member of the Disciplinary Committee hearing any case which has appeared before the Penal Cases Committee at which he was present as a member.

The attendance of witnesses and the production of documents before the Disciplinary Tribunal should be enforceable by subpoena, and evidence should be given on oath.

There should be a right of appeal to the High Court against the removal of a practitioner's name from the *Medical Register*.

If elected to the General Medical Council I shall press for such revision of medical education as will bring it into closer correspondence with the progress of knowledge and the requirements of modern practice.

My candidature has been endorsed by the Divisions of the B.M.A. in England and Wales. I assure you that if I am elected I shall devote to your service whatever time and energy may be necessary to the further fulfilment of my duty as Direct Representative. I ask you to accord me your vote, and I shall be grateful for your active assistance in securing the votes of your colleagues.

I submit my qualifications for the position of Direct Representative: I was Division Secretary for 23 years; I was a member of the Spens General Practitioners Committee; I am a member of Council British Medical Association and of the General Medical Services and Central Consultants and Specialists Committees.

Yours faithfully,

O. C. CARTER.

Hursley, Poole Road, Bournemouth.

SCOTTISH COMMITTEE

The first meeting of the new session of the Scottish Committee was held at B.M.A. Scottish House, Edinburgh, on October 4. Dr. I. D. Grant (Glasgow) was elected chairman in succession to Dr. George MacFeat (Lanarkshire), and Dr. J. G. M. Hamilton (Edinburgh) was elected deputy chairman.

In proposing the appointment of Dr. Grant as his successor, Dr. MacFeat commended the setting up of small study groups throughout the country to work on problems as they occurred locally. The groups, working through the machinery set up by the Association, could help towards practical solutions and influence future developments. In watching the development of the Health Service during the first year he had been deeply disturbed by the signs of deterioration in the position held by the general practitioner.

In accepting office, Dr. Grant paid tribute to the competent and unselfish service of Dr. MacFeat. Many members of the Scottish Committee, he said, had probably felt that much of its importance was removed when certain other committees became autonomous. It remained important, however, to have a widely representative body such as the Scottish Committee to watch the interests of all sections of the medical profession.

Dr. P. Martin Brodie (Edinburgh), Dr. I. Simson Hall (Edinburgh), and Dr. J. B. Miller (Bishopbriggs) were co-opted to the committee.

Alterations to the Scottish House

Dr. E. A. Cormack, chairman of the Building Subcommittee, and Mr. W. H. Kininmonth, architect, outlined the alterations and improvements proposed on the Scottish House property. These provide for more adequate accommodation for the meeting of members in both a business and social capacity. The reconstruction will provide improved accommodation not only for the Association but also for the Medical Insurance Agency. At present there are no catering facilities in the building, and it was proposed therefore to provide a members' dining-room. In the meantime snacks, light lunches, teas, etc., will be served. Mr. Kininmonth had estimated the cost, including equipment, at £15,000, but the final cost would probably be higher. The total cost of the project, including furnishings, would be about £20,000.

The Scottish Committee approved the plans and remitted the matter to the Central Building Committee.

Other Business

On the question of police fees, Dr. Grant said conditions in Scotland differed materially from those obtaining in England. He thought they might have a report on the position. The committee agreed that the Scottish Secretary should take the matter up with the Crown Office and thereafter submit a report to the Chairman's Subcommittee.

Representatives were appointed to meet the National Committee for the Training of Teachers on the question of equal pay for its medical officers.

A communication from the Ministry of Health on the setting up of Whitley Council machinery was remitted to the Whitley Council Subcommittee for consideration.

TRADE UNION MEMBERSHIP

The following is a list of local authorities which are understood to require employees to be members of a trade union or other organization:

Metropolitan Borough Councils.—Fulham, Hackney, Poplar.

Non-County Borough Councils.—Dartford, Wallsend.

Urban District Councils.—Denton, Droylsden, Houghton-le-Spring, Huyton-with-Roby, Redditch (restricted to new appointments), Tyldesley.

Correspondence

Status of General Practice

SIR,—I wish to endorse every word of Dr. Ian D. Grant's letter on the "Status of General Practice" (*Supplement*, October 1, p. 155). The feeling of dissatisfaction which is almost universal among general practitioners under the National Health Service is not entirely, or even mainly, financial in origin, but is due to the futility of a large part of their work, and to the feeling that their status in the Service is becoming lower and lower in the estimation of their specialist and administrative colleagues as well as the general public. Moreover, they themselves feel that their clinical ability is degenerating inasmuch as they are overwhelmed with trivial complaints and have little time and less incentive to improve the quality of their practice of medicine.

Such a state of affairs is inherent in the present set-up of the Service, and can only result in general practice procuring as its recruits the mediocre and the money-grubber; for no amount of financial inducement will attract a good doctor to a job which is a cross between a rubber-stamp and a finger-post.

What, then, can be done about it? Fundamentally there must be an inducement for the general practitioner to improve the quality of his work (and not only the quantity) and an opportunity to raise his professional prestige among his colleagues. A good man must be able to "get on" in the Service, and indeed I know of no other service in which this is not the rule.

I would suggest, therefore, that there be a grading of general practitioners according to their ability, experience, higher qualifications, etc., and that the higher grades would in some measure act in an advisory capacity to their more junior colleagues. Moreover, I would have specialists in most clinical subjects, and especially medicine, recruited from the ranks of general practice, where their vision and wisdom would be enlarged and where their knowledge of human ailments would become more catholic and not directed wholly along the narrow channels of their specialty, as it is now, almost from the date of their graduation. One sees so frequently nowadays the young specialist with great knowledge of disease and little of humanity, great technical skill and little judgment, great learning and little wisdom. I cannot think that this is a state of affairs to be encouraged.

Thus, although the system would not be rigid, the young graduate would normally enter the junior grades of general practice after completing one or two house appointments, and having proved himself in that sphere would have the opportunity of qualifying for the higher grades or branching off into an apprenticeship for his chosen specialty, which he would enter with some practical knowledge of general medicine.
